

Bail-ins and Bail-outs: Incentives, Connectivity, and Systemic Stability

Benjamin Bernard, Agostino Capponi, and Joseph E. Stiglitz*

This paper endogenizes intervention in financial crises as the strategic negotiation between a regulator and creditors of distressed banks. Incentives for banks to contribute to a voluntary bail-in arise from their exposure to credit and price-mediated contagion. In equilibrium, a bail-in is possible only if the regulator's threat to not bail out insolvent banks is credible. Contrary to models without intervention or government bailouts only, sparse networks are beneficial in our model for two main reasons: they improve the credibility of the regulator's no-bailout threat for large shocks and they reduce free-riding incentives among bail-in contributors when the threat is credible.

Financial institutions are linked to each other via bilateral contractual obligations and are thus exposed to counterparty risk of their obligors. If one institution defaults on its liabilities, it affects the solvency of its creditors. Since the creditors are also borrowers, they may not be able to repay what they owe and default themselves—problems in one financial institution spread to others in what is known as financial contagion. Large shocks can trigger a cascade of defaults, which impose negative externalities on the economy. The extent of these cascades—the magnitude of the systemic risk—depends on the nature of the linkages, i.e., the structure of the financial system. In the 2008 crisis, it became apparent that the financial system had evolved in a way which enhanced its ability to absorb small shocks but made it more fragile in the face of a large shock. While a few studies called attention to these issues before the crisis, it was only after the crisis that the impact of the network structure on systemic risk became a major object of analysis.¹ Most of the existing studies analyze the systemic risk implications of a default cascade, taking into account the network structure, asset liquidation costs, and different forms of inefficiencies that

Stiglitz: Columbia Business School, Columbia University, 3022 Broadway, Uris Hall 212, New York, NY 10027; jes322@gsb.columbia.edu. We are grateful to George Pennacchi (discussant), Yiming Ma (discussant), Asuman Ozdaglar, Alireza Tahbaz-Salehi (discussant), Darrell Duffie, Jakša Cvitanić, Matt Elliott, Douglas Gale, Matthew Jackson, Piero Gottardi, and Felix Corell for interesting discussions and perceptive comments. We would also like to thank the seminar participants of the Laboratory for Information and Decision Systems at the Massachusetts Institute of Technology, the Cambridge Finance Seminar series, the London School of Economics, Stanford University, New York University, the Fields Institute, the third annual conference on Network Science and Economics, the Columbia Conference on Financial Networks: Big Risks, Macroeconomic Externalities, and Policy Commitment Devices, the 2018 SFS Cavalcade North America, the 2019 American Finance Association meeting, and the 2018 North American Summer Meeting of the Econometric society for their valuable feedback. The research of Agostino Capponi is supported by a NSF-CMMI: 1752326 CAREER grant. Benjamin Bernard acknowledges financial support from grant P2SKP1.171737 by the Swiss National Science Foundation. Joseph Stiglitz acknowledges the support of the Columbia Business School and of the grant on Financial Stability from the Institute for New Economic Thinking.

¹Most notably, Allen and Gale (2000) and Greenwald and Stiglitz (2003). See also Boissay (2006), Castiglionesi (2007), May, Levin and Sugihara (2008), and Nier et al. (2007). One of the reasons for the limited study is the scarce availability of data on interbank linkages.

arise at default. Many of these models, however, do not account for the possibility of intervention to stop the cascade. There is either no rescue of insolvent banks or the regulator (or central bank or other government institution) intervenes by following an exogenously specified protocol. The goal of our paper is to endogenize the intervention mechanism as the equilibrium outcome of the strategic interaction between regulator and financial institutions. We show that endogenizing the intervention plan affects the socially desirable network structure.

The most common default resolution procedure during the 2007–2009 financial crisis was the *bailout*.² In a bailout, the government injects liquidity to help distressed banks service their debt, effectively transferring liabilities from the private sector to the public sector. For example, the U.S. Treasury Department’s Troubled Asset Relief Program (TARP) authorized expenditures of \$700 billion to prevent fire sale losses. (See also Duffie (2010) for a related discussion.) Some governments, such as Germany’s, have called for private-sector participation through *bail-ins*, in which creditors write down their interbank claims against troubled banks.³ Bail-ins effectively amount to a transfer of liabilities within the private sector, which places the burden of losses on creditors as opposed to taxpayers. A prominent example of a bail-in is the consortium organized by the Federal Reserve Bank of New York to rescue the hedge fund Long-Term Capital Management.⁴ In our paper, we will also consider *assisted bail-ins*, in which the regulator provides some liquidity assistance to incentivize the formation of a bail-in.

We model the provision of liquidity assistance as a three-stage sequential game between regulator and the banks. In the first stage, the regulator proposes an assisted bail-in allocation, which specifies the contributions by each solvent bank, as well as the additional liquidity injections that he will provide to each bank. In the second stage, each bank decides whether or not to participate in the proposed rescue. If all designated participants accept, the game ends with the proposed rescue consortium. Otherwise, the game proceeds to the third stage, in which the regulator chooses among three options: (i) use taxpayer money to contribute the debt amount that was supposed to be forgiven by the banks which rejected the proposal, (ii) abandon the bail-in coordination and resort to a public bailout, or (iii) avoid any intervention. After transfers are made, the banks’ liabilities are cleared simultaneously in the spirit of Eisenberg and Noe (2001), possibly leading to a default cascade if the outcome of the negotiation leaves some banks insolvent.

Financial contagion in our model occurs through *price-mediated contagion* and *credit contagion*, the two most prominent channels of contagion identified by historical events.⁵ First, distressed

²The Bush administration bailed out large financial institutions (AIG insurance, Bank of America, Bear Stearns and Citigroup) and government sponsored entities (Fannie Mae, Freddie Mac) at the heart of the crisis. The European Commission intervened to bail out financial institutions in Greece and Spain.

³In spite of such calls and the design of instruments to make private-sector participation automatic, there have been few successful bail-ins. Automatic participation is implemented through the use of “bail-inable debt” such as contingent-convertible bonds in order to reduce the banks’ credit risk. The focus of this paper is on the welfare impact of default resolution policies after these risk-mitigating instruments have already been used.

⁴Long-Term Capital Portfolio collapsed in the late 1990s. On September 23, 1998, a recapitalization plan of \$3.6 billion was coordinated under the supervision of the Federal Reserve Bank of New York. A total of fourteen banks agreed to participate and two banks (Bear Stearns and Lehman Brothers) rejected the proposal.

⁵Quoting Greenspan (1998): “It was the judgment of officials at the Federal Reserve Bank of New York, who were monitoring the situation on an ongoing basis, that the act of unwinding LTCM’s portfolio in a forced liquidation would not only have a significant distorting impact on market prices but also in the process could produce large losses, or worse, for a number of

banks may have to liquidate some of their asset holdings in order to fulfill their obligations. Doing so over a short time period will have a knock-on effect on the asset price, causing losses to other holders of the asset. If several banks liquidate the asset simultaneously, this leads to a self-reinforcing mechanism, where a price drop forces banks to sell more in order to raise the needed liquidity, causing further price drops, and so on. Second, if a distressed bank defaults on its obligations, it will transmit losses to its creditors. Bankruptcy imposes deadweight losses, which are amplified by the feedback loops among defaulting banks.

We investigate the structure of default resolution plans that arise in equilibrium when the regulator cannot credibly commit to an ex-post suboptimal resolution policy. The lack of commitment power has important consequences for the regulator’s negotiation power: if banks are aware that without their participation, the regulator prefers a bailout over no intervention, then they have no incentive to participate in any assisted bail-in the regulator proposes. We say that, in this case, the regulator’s *no-intervention threat* fails to be credible.⁶ Only if the threat is credible can an assisted bail-in be organized in equilibrium. Individually, a bank is willing to contribute up to the maximum it would lose in a default cascade. However, because losses are amplified as the shock propagates through the system, losses exceed the required ex-ante contributions. Therefore, it is not necessary that every bank contributes and banks have an incentive to free-ride on the contributions of others. In the equilibrium bail-in, the set of contributing banks minimizes free-riding incentives by consisting of the banks with the largest exposure to contagion. It thus follows that banks are willing to contribute more in sparser networks: because losses are more concentrated, the benefits of a bail-in are more targeted to the contributors than in more diversified networks, thereby reducing free-riding incentives.

A key determinant of the equilibrium outcome is the credibility of the regulator’s no-intervention threat. We show that it is credible if and only if the losses generated by the regulator’s inaction—equal to the amplification of the shock as it propagates through the network—does not exceed a given threshold. Whether the shock amplification increases with the size of the initial shock faster than the threshold rises depends on asset illiquidity and on the network structure. We identify a variable, which we call the *total throughput* of defaulting banks, as a sufficient statistic for the dependence of the credibility on the network structure, conditional on the banks’ levels of solvency and their total claims on solvent banks. The total throughput measures the rate of spillover losses transmitted to the solvent banks in the system. Conditional on the banks’ solvency, the total throughput depends only on the network structure and not the banks’ balance sheet quantities, making it a particularly convenient measure to compare different networks’ potential to propagate losses. We demonstrate that the throughput increases as the connectivity of defaulting banks increases. As a result, in sparsely connected networks, the regulator’s threat may not be credible for small shocks, but the credibility improves as the shock grows larger. Because the total

creditors and counterparties, and for other market participants who were not directly involved with LTCM. In that environment, it was the FRBNY’s judgment that it was to the advantage of all parties—including the creditors and other market participants—to engender if at all possible an orderly resolution rather than let the firm go into disorderly fire-sale liquidation following a set of cascading cross defaults.”

⁶Several attempted bail-ins failed because the threat of not undertaking a bail-out was not credible; see Stiglitz (2002).

Figure 1: The figure compares equilibrium welfare losses in a diversified (blue) and a concentrated network (red) in the presence (solid lines) and absence (dashed lines) of intervention.⁷ Because the total throughput is small (large) in sparse (dense) networks, welfare losses in absence of intervention are concave (convex). When the no-intervention losses exceed the costs of a public bailout (black dashed line), the government’s threat to not intervene fails to be credible and a public bailout is the only possible equilibrium rescue. If the threat is credible, contributions from the private sector are possible. Contributions are larger in the sparse network because losses without intervention are more concentrated, thereby reducing free-riding incentives. Without intervention or in a model with bailouts only, the diversified network is preferable up until shock size S_2 . Endogeneity of the intervention reverses the relative desirability of the two network structures for intermediate shock sizes between S_1 and S_2 .

throughput is small, the systemic threat does not increase much with the size of the shock. By contrast, in more diversified network structures, small losses can be well absorbed and the threat not to intervene is credible. However, because the total throughput is large, the threat becomes less credible as the shock size increase. As illustrated in Figure 1, endogeneity of the default resolution plan thus reverses the relative desirability of network structures for intermediate shock sizes when compared to models without intervention or models with bailouts only.

In any intervention plan—bail-in or bailout—the regulator trades off the cost of taxpayer contributions with the fire-sale losses caused by inefficient asset liquidation and broader societal losses from a bankruptcy cascade. In a bail-in, this trade-off is further affected by the size of the banks’ incentive-compatible contributions, which are increasing in the attained price: the higher the asset price under the proposed resolution, the more attractive this resolution becomes relative to the default cascade where asset prices would collapse. The regulator thus sustains a higher asset price in a bail-in than in a bailout. We show that banks, in fact, benefit from additional market illiquidity. Not only does it decrease the credibility of the regulator’s threat not to intervene, but the larger potential knock-on effects on the asset price also warrant larger liquidity assistance from the regulator. This results in a net increase of asset prices—at the cost of taxpayer contributions. These findings imply that banks have an incentive to specialize in thinly-traded assets. Policies which require banks to hold a certain proportion of highly liquid assets, such as the liquidity coverage ratio, thus help improve the credibility of the no-intervention threat.

We then proceed to investigate the structure of optimal intervention plans, that is, the set of banks that are rescued. A bank is not rescued in a bailout if the loss-absorption capacity of its creditors is high enough to absorb a significant portion of the losses due to contagion. In a bail-in, not only the total loss absorption capacity matters but also its distribution among the creditors. When a bank has a single creditor, that creditor cannot free-ride on the contributions of others. Proposing a bail-in for a bank whose losses are absorbed by a single creditor thus leads to an increase in welfare. However, if contagion effects are spread among many creditors, rescuing that

bank does not substantially increase contributions from the private sector because of the banks' inherent free-riding incentives. It may then be welfare-enhancing to not rescue such a bank. Banks rescued in the optimal bail-in may thus default in the optimal bailout and vice versa.

Our results uncover the economic forces behind the decision to rescue banks which default due to idiosyncratic fundamental shocks versus those failing as a result of contagion. For example, the government opted to rescue AIG as opposed to Goldman Sachs during the global financial crisis.⁸ Because loss absorption capacities were low in the aftermath of Lehman Brother's default, bankruptcy filings of AIG might have had far-reaching consequences, bringing under many of its creditors including Goldman Sachs. If the financial system had been in a more resilient state, in which Goldman Sachs was the only contagiously defaulting bank, it might have been welfare-enhancing to let AIG default and provide liquidity assistance only to Goldman Sachs after the depletion of Goldman's capital buffers.

The remainder of the paper is organized as follows. In Section 1, we put our work in perspective with the existing literature. We develop the model in Section 2. We characterize incentives and the equilibrium intervention outcome for any financial network in Section 3. We analyze the impact of the network structure, the shock size, and asset illiquidity on the public bailout and the credibility in Section 4. In Section 5, we characterize the set of banks to be optimally rescued in bail-ins and bailouts. We discuss the impact of the network structure on the equilibrium intervention plan in Section 6 using a model calibrated to a data set of the European Banking Authority (EBA). Section 7 concludes. The proofs of the main results are contained in the appendix. Supplementary results and auxiliary proofs are in the online appendix Bernard, Capponi and Stiglitz (2019).

1 Literature Review

Our paper is related to a vast branch of literature on financial contagion in interbank networks. Pioneering works include Allen and Gale (2000) and Eisenberg and Noe (2001), and further developments were made in more recent years by Acemoglu, Ozdaglar and Tahbaz-Salehi (2015), Elliott, Golub and Jackson (2014), Gai, Haldane and Kapadia (2011), Glasserman and Young (2015), and Capponi, Chen and Yao (2016). We refer to Glasserman and Young (2016) for a thorough survey on financial contagion.⁹ These works study how an initial shock is amplified through the interbank network based on the network structure, the inefficient liquidation of non-interbank assets, the trade-off between diversification and integration on the level of interbank exposures, and the complexity of the network. Different from our study, in these models agents execute exogenously specified contractual agreements but do not take any strategic action to resolve distress in the net-

⁸The bailout of AIG was widely speculated to be an indirect bailout of Goldman Sachs, to which it had sold millions of dollars worth of insurance. Because of the large exposure, AIG's default might have lead to the contagious default of Goldman Sachs, the largest investment bank at the time.

⁹Other related contributions include Gai and Kapadia (2010), which analyze how knock-on effects of distress can lead to write down the value of institutional assets; Cifuentes, Ferrucci and Shin (2005), which analyze the impact of fire sales on financial network contagion; Cabrales, Gottardi and Vega-Redondo (2017), which study the trade-off between the risk-sharing generated by more dense interconnection and the greater potential for default cascades; Battiston et al. (2012), which demonstrate that systemic risk does not necessarily decrease if the connectivity of the underlying financial network increases; and Elsinger, Lehar and Summer (2006), which study transmission of contagion in the Austrian banking system;

work. A different branch of the literature has focused on the coordinating role of the central bank in stopping financial contagion through provision of liquidity (Freixas, Parigi and Rochet (2000) and Gorton (2010)). These studies, however, do not consider resolution strategies that involve the private sector, such as the bail-ins considered in our paper. The viability of private-sector involvement depends on the credibility of the no-intervention commitment by the government, which we show to be tightly linked to the network structure. The importance of integrating bottom up approaches based on network models and top down frameworks that design regulatory measures is stressed in a recent survey on systemic risk by Benoit et al. (2017).

In our model, the regulator determines the optimal rescue plan after the banks have already decided on the amount of risk undertaken, and shocks to outside assets have occurred. We do not consider here the moral hazard problem of banks taking excessive risks, knowing that they will be rescued if the market moves against them. Moral hazard problems arising in this context have been thoroughly investigated in the literature, though not in the context of a strategic bail-in policy. Doing so represents a next step in our research agenda, discussed briefly in Section 7. Important contributions include Gale and Vives (2002), who argue that a bailout is optimal ex post, but ex ante it should be limited to control moral hazard; Acharya and Yorulmazer (2007), who show that banks may find it optimal to invest in highly correlated assets in anticipation of a bailout triggered by the occurrence of many simultaneous failures; Farhi and Tirole (2012), who support Acharya and Yorulmazer (2007)'s findings by showing that safety nets can provide perverse incentives and induce correlated behavior that increases systemic risk; Chari and Kehoe (2016), who show that if the regulator cannot commit to avoid bailouts ex post, then banks may overborrow ex ante; and Keister (2016), who finds that prohibiting bailouts may lead intermediaries to invest into too liquid assets which lower aggregate welfare. Our model, like the rest of the literature on default resolution policies in financial networks, does not account for the endogenous structure of the interbank network. The exception is a recent study by Erol (2018), which develops an endogenous network formation model in the presence of government bailouts. Different from Erol (2018), the regulator in our model is strategic and cannot commit to a bailout or a no-intervention policy.

Related to our model is the study by Rogers and Veraart (2013), which analyze situations in which banks can stop the insolvency from spreading by stabilizing the financial system through mergers. In their paper, however, a merger need not be incentive compatible for the shareholders of an individual bank and the government does not take an active role. By contrast, our model focuses on the credibility of the regulator's actions and the free-riding problem that arises because the stability of the financial system is to the benefit of every participant. Duffie and Wang (2017) consider a bargaining model, in which bail-ins are done contractually rather than through a central planner. Unlike our paper, they crucially assume the absence of cross-network externalities. In the limit as disagreement is disallowed, Duffie and Wang (2017) show that the bargaining equilibrium in a 3-bank network is efficient. In our paper, externalities from asset liquidation and bankruptcy losses are at the heart of the analysis, driving our characterization of the endogenous ex-post default resolution plan that arises from the negotiation between regulator and financial institutions.

2 Model

We consider an economy consisting of n risk-neutral financial institutions $i = 1, \dots, n$, called “banks”, which lasts for three periods $t = 0, 1, 2$. At the initial period, each bank i is endowed with capital that it can lend to other banks, invest into a liquid asset, called “cash”, or invest into an illiquid asset, yielding a random return at time $t = 1$ and a non-pledgeable return at $t = 2$. Because long-term returns are non-pledgeable, liabilities have to be cleared at time $t = 1$. After short-term returns are realized, banks may liquidate their risky assets to help service their debt, but because of market illiquidity, doing so will cause a downward impact on the asset’s price.

Banks negotiate debt contracts with each other at $t = 0$. We denote by L^{ji} bank i ’s liabilities to bank j at time $t = 1$ and use $L^i := \sum_{j=1}^n L^{ji}$ to denote bank i ’s total interbank liabilities. Let p^i denote the market value of bank i ’s liabilities. This market value may be lower than the notional value L^i because bank i may be unable to repay its liabilities in full. If $p^i < L^i$, we say that bank i defaults. All interbank liabilities have equal seniority: if bank i defaults, each creditor j receives $\pi^{ji} p^i$ from bank i , where

$$\pi^{ji} = \begin{cases} L^{ji}/L^i & \text{if } L^i > 0, \\ 0 & \text{otherwise.} \end{cases}$$

The relative liability matrix $\pi = (\pi^{ij})_{i,j=1,\dots,n}$ captures the structure of the financial network. In addition to its liabilities within the financial network, bank i has financial commitments w^i outside the financial sector due at time $t = 1$, which have higher seniority than the interbank liabilities. These commitments include wages, depositors’ claims, and other operating expenses.¹⁰

For each bank i , we denote by e^i the long-term returns of the illiquid asset held by i . We denote by c^i the sum of i ’s cash holdings and the short-term returns realized at time $t = 1$. If a bank i is not able to meet its liabilities out of current income, it will liquidate a portion $\ell^i \in [0, e^i]$ of its illiquid asset. Liquidation imposes a downward impact on the price α of the asset given by

$$\alpha(\ell) = \exp\left(-\gamma \sum_{i=1}^n \ell^i\right), \tag{1}$$

where $\gamma \geq 0$ is the elasticity of the asset price.¹¹ A defaulting bank liquidates all of its assets to repay the maximal amount to its creditors. Because liquidation is costly, a solvent bank liquidates just enough to meet its liabilities. When prices are equal to (p, α) , bank i thus liquidates an amount

$$\ell^i(p, \alpha) = \min\left(\frac{1}{\alpha} \left(L^i + w^i - c^i - \sum_{j=1}^n \pi^{ij} p^j\right)^+, e^i\right), \tag{2}$$

¹⁰Our framework can accommodate lending from outside the financial sector with equal seniority as interbank liabilities by adding a “sink node” that has only interbank assets but no interbank liabilities.

¹¹Such a downward sloping inverse demand function has also been used in Cifuentes, Ferrucci and Shin (2005). For this choice of inverse demand function, the infinitesimal price impact is proportional to the asset’s price. The elasticity parameter γ typically depends on the asset class: Ellul, Jotikasthira and Lundblad (2011) find that γ is in the order of 10^{-8} for corporate bonds (see Table 8 therein).

where $(\cdot)^+ = \max(\cdot, 0)$ denotes the positive part.¹² If a bank i cannot meet its liabilities even after liquidating all of its assets, it will default. The default creates losses proportional to the banks' asset value: only a fraction $\beta \in (0, 1]$ of the bank's asset value is paid to the creditors and a fraction $(1 - \beta)$ is lost.¹³ The market value of bank i 's interbank liabilities is thus equal to

$$p^i = \begin{cases} L^i & \text{if } c^i + \alpha \ell^i + (\pi p)^i \geq L^i + w^i, \\ (\beta(c^i + \alpha e^i + (\pi p)^i) - w^i)^+ & \text{otherwise,} \end{cases} \quad (3)$$

where $(\pi p)^i = \sum_{j=1}^n \pi^{ij} p^j$ is the market value of bank i 's interbank claims. How much a bank is able to repay depends on the solvency of the other banks in the system. In a clearing equilibrium, every solvent bank repays its liabilities in full and every insolvent bank pays its entire value (after bankruptcy costs) to its creditors.

The financial system in our model is parametrized by $(L, \pi, e, c, w, \gamma, \beta)$, where L, e, c , and w are vectors whose entries are the corresponding balance sheet quantities of each bank.

Definition 2.1. A set of prices and liquidation decisions (p, ℓ, α) is a *clearing equilibrium* for a financial system $(L, \pi, e, c, w, \gamma, \beta)$ if it satisfies (1)–(3).

When prices are equal to (p, α) , the value of bank i 's equity is given by

$$V^i(p, \alpha) := ((\pi p)^i + c^i + \alpha e^i - w^i - L^i)^+. \quad (4)$$

If the payment p^i made by bank i is positive, it is divided pro-rata among bank i 's junior creditors and the senior creditors are paid in full. If $p^i = 0$, the junior creditors lose the full amount of their claims and the senior creditors of bank i suffer a loss of

$$\delta^i(p, \alpha) := (w^i - \beta(c^i + \alpha e^i + (\pi p)^i))^+, \quad (5)$$

We denote by $\mathcal{D}(p, \ell, \alpha) := \{i \mid L^i + w^i > c^i + \alpha \ell^i + (\pi p)^i\}$ the set of defaulting banks. Welfare losses in a clearing equilibrium are defined as the weighted sum of default costs, i.e.,

$$W_\lambda(p, \ell, \alpha) := (1 - \alpha) \sum_{i=1}^n e^i + (1 - \beta) \sum_{i \in \mathcal{D}(p, \ell, \alpha)} (c^i + \alpha e^i + (\pi p)^i) + \lambda \sum_{i \in \mathcal{D}(p, \ell, \alpha)} \delta^i(p, \alpha). \quad (6)$$

The first term are losses due to fire sales, and the second term quantifies deadweight losses from bankruptcy. Losses of senior creditors are weighted by a factor $\lambda \geq 0$, which captures the importance the regulator assigns to the senior creditor's losses relative to deadweight losses. A regulator with $\lambda = 0$ views losses of senior creditors simply as transfers of wealth and not as losses to the economy. A higher value of λ indicates a higher priority to the economy outside of the banking sector.

¹²The model can be adjusted to account for liquidity requirements such as Basel-III (2013). This can be achieved by setting c^i equal to the amount of liquid assets that can be liquidated before hitting the liquidity coverage ratio requirement.

¹³According to Moody's analysis, the average recovery rate for unsecured corporate bonds ranges from 30% to 43%; see Exhibit 8 in <https://www.moody.com/sites/products/DefaultResearch/2006600000428092.pdf>.

Every financial system admits a clearing equilibrium as a consequence of Tarski's fixed-point theorem. Cifuentes, Ferrucci and Shin (2005) show that it is unique under mild regularity conditions if $\beta = 1$. This is no longer the case in the presence of bankruptcy costs, i.e., when $\beta < 1$. Following standard practices in the literature, liabilities are then cleared with the unique Pareto-dominant clearing equilibrium.

Lemma 2.1. *For any financial system, there exist a greatest and a lowest clearing equilibrium $(\bar{p}, \bar{\ell}, \bar{\alpha})$ and $(\underline{p}, \underline{\ell}, \underline{\alpha})$, respectively, with $\bar{p}^i \geq p^i \geq \underline{p}^i$, $\bar{\ell}^i \leq \ell^i \leq \underline{\ell}^i$, and $\bar{\alpha}^i \geq \alpha^i \geq \underline{\alpha}^i$ for any clearing equilibrium (p, ℓ, α) and any bank i . Moreover, $(\bar{p}, \bar{\ell}, \bar{\alpha})$ is Pareto dominant for any $\lambda \geq 0$, that is, for any clearing equilibrium (p, ℓ, α) , we have $V^i(\bar{p}, \bar{\alpha}) \geq V^i(p, \alpha)$ for all i and $W_\lambda(\bar{p}, \bar{\ell}, \bar{\alpha}) \leq W_\lambda(p, \ell, \alpha)$.*

2.1 Contagion and Default Cascade

We position ourselves at time $t = 1$, when short-term returns have been realized but banks have not yet cleared their liabilities. Our objective is to characterize the endogenous intervention outcome after any realization of market returns. We consider voluntary bail-ins, so that if the banks and/or the regulator have implemented automatic bail-in triggers such as, for example, contingent convertible bonds, then $(L, \pi, e, c, w, \alpha, \beta)$ represents the state of the financial system after accounting for these risk-mitigating actions. Depending on the size of the shock, banks may still need to dispose of their illiquid assets to remain solvent and defaults may still occur.

There are two channels of financial contagion in our model. The first channel is price-mediated contagion. When a distressed bank needs to liquidate the asset, the price declines due to market illiquidity, captured in reduced from through (1). As a consequence, other banks which hold the asset experience a reduction of their equity value. If the price impact from asset sales is sufficiently large, other banks may also need to liquidate some of their asset to stay solvent, thereby further depressing the price. This leads to a downward spiral, which converges to the highest price, for which the asset's demand—given by the inverse of (1)—equals the amount liquidated.

Lemma 2.2. *For any vector p of repayments, there exists a solution (α_p, ℓ_p) to (1) and (2) such that $\alpha \leq \alpha_p$ for any other solution (α, ℓ) to (1) and (2).*

The second channel of contagion in our model is *credit contagion*. A defaulting bank i reduces the payments to its creditors, thereby imposing losses $L^i - p^i$ to the rest of the financial system. Creditors with large interbank exposures may thus default as a consequences of these losses. This, in turn, may affect the solvency of their creditors and so on, causing a cascade of defaults. The cascade starts with the set $\mathcal{F} := \{i \mid c^i + \alpha_L \ell_L^i + (\pi L)^i < L^i + w^i\}$ of *fundamentally defaulting banks*, i.e., the set of banks that are unable to repay their liabilities even if every other bank repays its liabilities in full. If there are no fundamentally defaulting banks, then (L, ℓ_L, α_L) is the Pareto-efficient clearing equilibrium and all interbank liabilities are honored.

2.2 Coordination of Rescues

As argued in the preceding section, financial stability can be ensured by injecting sufficient liquidity into the fundamentally defaulting banks so that they can meet their liabilities. In a bailout, this additional liquidity is provided by the government through taxpayer contributions, whereas in a bail-in, creditors of insolvent banks voluntarily take a haircut on their claims. As an intermediate option between the two, we also consider assisted bail-ins, which include transfers by both the banks and the government.

Definition 2.2. An *assisted bail-in* (b, s) specifies, for each bank i , the contribution b^i to be made by i and the size s^i of the subsidy i receives. The government's contribution to the bail-in is $\sum_{i=1}^n (s^i - b^i)$, which is imposed to be non-negative.¹⁴

Observe that assisted bail-ins contain bailouts and privately backed bail-ins as special cases. A bailout is the limiting case of an assisted bail-in, in which the banks' contributions are equal to zero. In a private bail-in, the government contributions are zero. In addition to contributing to a bail-in financially, the regulator also serves to coordinate among different bail-ins. Specifically, the regulator may propose a bail-in allocation, but cannot force banks to participate.

Organization of a rescue.

1. The regulator proposes an assisted bail-in (b, s) .
2. Each bank i from the set $\mathcal{A}(b) := \{j \notin \mathcal{F} \mid b^j > 0\}$ chooses a binary action $a^i \in \{0, 1\}$, indicating whether or not it agrees to contribute b^i .¹⁵
3. The regulator chooses his response r from the following three options:
 - (i) "*bail-in*": Proceed with the proposed subsidies s , using taxpayer money to cover the contributions of banks which rejected the proposal. Cash holdings and financial commitments of each bank i are then equal to $c^i(s) := c^i + s^i$ and $w^i(b, a) := w^i + b^i 1_{\{a^i=1\}}$ and the resulting financial system is cleared as in Section 2. We denote by $\bar{p}(b, s, a)$ and $\bar{\alpha}(b, s, a)$ the prices in the Pareto-dominant clearing equilibrium. Bank i 's equity value is equal to $V^i(\bar{p}(b, s, a), \bar{\alpha}(b, s, a))$. Welfare losses are obtained from (6) by additionally accounting for the social cost of government subsidies, that is,

$$W_\lambda(b, s, a) := W_\lambda(\bar{p}(b, s, a), \bar{\ell}(b, s, a), \bar{\alpha}(b, s, a)) + \lambda \sum_{i=1}^n (s^i - b^i 1_{\{a^i=1\}}).^{16} \quad (7)$$

¹⁴This formulation is equivalent to a formulation, in which creditors write down their claims on insolvent banks such that b^i is the net debt forgiven by bank i and s^i is the sum of government injections and net debt forgiven to bank i by i 's creditors.

¹⁵We assume that a bank i with $b^i = 0$ is simply not part of the negotiation and hence has no power to reject the proposal. For ease of notation, we write $a^i = 1$ for such a bank.

¹⁶We assume that the regulator assigns the same weight to taxpayer contributions as to losses of senior creditors. This assumption is made for notational convenience and our results would hold if the regulator used different weights.

- (ii) “*bailout*”: Resort to a public bailout $(0, \tilde{s})$ with subsidies \tilde{s} decided by the regulator. Then, cash holdings of bank i are equal to $c^i(\tilde{s}) = c^i + \tilde{s}^i$ and we denote by $\bar{p}(\tilde{s})$ and $\bar{\alpha}(\tilde{s})$ the prices in the Pareto-dominant clearing equilibrium. Each bank i 's equity value is $V^i(\bar{p}(\tilde{s}), \bar{\alpha}(\tilde{s}))$ and welfare losses are denoted by $W_\lambda(\tilde{s}) := W_\lambda(0, \tilde{s}, 0)$.
- (iii) “*no intervention*”: Abandon the rescue, which results in the default cascade of Section 2. We denote by (p_N, ℓ_N, α_N) the Pareto-dominant clearing equilibrium and by W_N the welfare losses in the default cascade.

Remark 2.1. Some banks may be left with zero equity after they are bailed in or bailed out. Such banks cease to exist as a separate entity after the intervention and their bail-ins or bailouts should be understood as an orderly liquidation through takeovers by the bail-in contributors or the government.¹⁷ Because these banks have zero equity value after the intervention, we do not model how the assets are distributed among contributors.

A strategy of each bank i is a map $a^i(b, s)$ that specifies for each proposal whether or not i agrees to participate. The regulator's strategy consists of which bail-in (b, s) to propose, as well as a reaction $r(b, s, a)$ to any given response vector a by banks. Our solution concept is that of subgame Pareto efficient equilibria, defined as follows.

Definition 2.3. A strategy profile (b, s, a, r) is *subgame Pareto efficient* if it is subgame perfect and after any proposal (b, s) , there is no other continuation equilibrium (\tilde{a}, \tilde{r}) of the accepting/rejecting subgame that Pareto dominates (a, r) for the banks in $\mathcal{A}(b)$ and the regulator.

This equilibrium solution concept is meant to capture the interactions between the regulator and the banks in $\mathcal{A}(b)$, aiming at finding a suitable resolution outcome. For example, during the bail-in of Long-Term Capital Management, Peter Fisher of the Federal Reserve Bank of New York sat down with representatives of LTCM's creditors to find an appropriate solution; and it is implausible that they would have agreed on a bail-in plan that is Pareto dominated. Note that banks in the complement of $\mathcal{A}(b)$ are potentially worse off than in an alternative continuation equilibrium of the accepting/rejecting subgame because they are not part of the discussion.

Any proposal of the regulator admits an equilibrium response by the banks by the following lemma. This result also implies existence of subgame Pareto efficient equilibria in our model.

Lemma 2.3. *After any proposal (b, s) , there exists a Pareto efficient continuation equilibrium (a, r) of the accepting/rejecting subgame.*

Because subgame Pareto efficiency is a refinement of subgame perfection, the regulator lacks commitment power: it eliminates the non-credible threat of the regulator to abandon the rescue in the third stage when, in fact, a public bailout leads to lower welfare losses than a default cascade. This restricts the regulator's ability to incentivize banks to contribute as we discuss in Section 3.2.

¹⁷Examples of such takeovers from the global 2007–2009 financial crisis are plentiful. Among the most prominent ones are the takeovers of Bear Stearns and Merrill Lynch by JP Morgan Chase and Bank of America, respectively, or the federal takeovers of Fannie Mae and Freddie Mac.

In our model, the regulator knows the financial position of each bank and, thus, he can anticipate the banks' responses to any bail-in proposal. Therefore, he need not make a proposal that is not incentive compatible and the negotiation is collapsed into a single stage. In reality, the regulator typically is not fully informed and the coordination of a bail-in might take the form of a strategic bargaining game instead. Some banks might reject the regulator's initial proposal, after which the regulator revises his proposal to either exclude those banks or to accommodate them.¹⁸

We may assume without loss of generality that the regulator proposes only so-called feasible bail-ins, in which every bank can afford the proposed contribution.

Definition 2.4. A bail-in proposal (b, s) is *feasible* if $b^i = 0$ for any fundamentally defaulting bank $i \in \mathcal{F}$ and $L^i + w^i + b^i \leq c^i + s^i + \bar{\alpha}(b, s, 1)\ell^i(b, s, 1) + \sum_{j=1}^n \pi^{ij}\bar{p}^j(b, s, 1)$ for any bank $i \notin \mathcal{F}$, where $1 = (1, \dots, 1)$ is the response of unanimous agreement.

Since prices are weakly decreasing with the banks' contributions, feasibility of a bail-in (b, s) implies that $L^i + w^i + b^i \leq c^i + s^i + \bar{\alpha}(b, s, a)\ell^i(b, s, a) + \sum_{j=1}^n \pi^{ij}\bar{p}^j(b, s, a)$ also for any response vector $a \neq (1, \dots, 1)$. Therefore, whether a bank can afford to contribute to a feasible bail-in does not depend on the responses of the other banks. Key is the fact that if some bank i refuses to participate but the regulator decides to implement the bail-in nonetheless, then the regulator uses additional taxpayer money to make up for i 's contribution. Feasibility of a proposed bail-in thus provides banks with a guarantee that prices will be *at least* $\bar{p}(b, s, 1)$ and $\bar{\alpha}(b, s, 1)$ —backed by government contributions if necessary; see Lemma F.3 in the online appendix for details.¹⁹

3 Incentives and Credibility of Intervention Plans

To highlight the primary economic forces at play, we focus on the case of what we call *complete* interventions in this section, where the regulator considers only bailouts and bail-ins that rescue every bank in the system. Section 5 treats the more general case where the regulator can propose interventions that rescue some banks but not others, and discusses the additional economic trade-offs arising in the equilibrium outcome.

3.1 Public Bailout

In a complete bailout, the regulator provides subsidies to support the clearing payment vector L . The smallest subsidies necessary are those required to make every bank solvent, which are equal to

$$s_L := (L + w - c - \alpha_L \ell_L - \pi L)^+,$$

¹⁸The original proposal made by the Federal Reserve Bank of New York for the rescue of Long Term Capital Management involved a total of 16 of LTCM's creditors. However, Bear Stearns and Lehman Brothers later declined to participate. Upon the rejection of these two banks, the Fed adjusted its proposal so that the contributions of Bear Stearns and Lehman Brothers were covered by the remaining 14 banks. The fact that these two banks decided not to cooperate shows that participation in the bail-in was at least partially voluntary.

¹⁹In reality, asset price guarantees are often given through collateral. This was the case in the purchase of Bear Stearns by JP Morgan Chase, where the government provided a large collateral for Bear Stearns' assets.

where (α_L, ℓ_L) is given by Lemma 2.2. If asset liquidation is more costly than taxpayer contributions, the regulator will want to provide additional subsidies up to

$$s_0 := (L + w - c - \pi L)^+ \quad (8)$$

so that no bank liquidates any of its assets. Note that subsidies s_L and s_0 support the clearing equilibria (L, ℓ_L, α_L) and $(L, 0, 1)$, respectively. The welfare-maximizing subsidies s in a complete bailout are such that the marginal losses from liquidation are as close to the marginal welfare cost λ of taxpayer contributions as possible, given the constraints $s_L^i \leq s^i \leq s_0^i$, which guarantee solvency of every bank in the system.

Lemma 3.1. *Define the function $g(\alpha) = \alpha(\frac{\lambda}{\gamma} \ln(\alpha) - \sum_{i=1}^n e^i)$. In any complete bailout with subsidies $s^i \leq s_0^i$ for every bank i , welfare losses are equal to*

$$W_\lambda(s) = \sum_{i=1}^n (e^i + \lambda s_0^i) + g(\bar{\alpha}(s)). \quad (9)$$

The regulator's choice of subsidies affects welfare only through the induced asset price as the argument of the function g , which captures the welfare trade-off between liquidation costs and taxpayer contributions. Any bailout that induces asset price α requires banks to liquidate an aggregate amount $-\ln(\alpha)/\gamma$ as seen in (1). This corresponds to a reduction of the maximal subsidies s_0 by the market value of those liquidated assets. Choosing subsidies that induce asset price α (as opposed to s_0) thus lower welfare costs by $-\lambda\alpha \ln(\alpha)/\gamma$ but increase liquidation losses by $\alpha \sum_{i=1}^n e^i$. The function g is convex and it is minimized at the *indifference price*

$$\alpha_{\text{ind}} := \exp\left(\frac{\gamma}{\lambda} \sum_{i=1}^n e^i - 1\right). \quad (10)$$

If $\alpha < \min(\alpha_{\text{ind}}, 1)$, liquidation is more costly than taxpayer contributions, hence the regulator will provide additional subsidies to drive the price up to $\min(\alpha_{\text{ind}}, 1)$. If $\alpha > \alpha_{\text{ind}}$, asset liquidation is considered cheaper than taxpayer contributions, hence the regulator will reduce the size of the provided subsidies (to a minimum of s_L) to drive the price down to $\min(\alpha_{\text{ind}}, \alpha_L)$.

Lemma 3.2. *Let $\alpha_P = \max(\min(\alpha_{\text{ind}}, 1), \alpha_L)$. A welfare-maximizing complete bailout awards subsidies s with $s_L^i \leq s^i \leq s_0^i$ for every bank i such that*

$$\sum_{i=1}^n s^i = \sum_{i=1}^n s_0^i + \frac{\alpha_P \ln(\alpha_P)}{\gamma}. \quad (11)$$

These subsidies induce asset price α_P . We denote by W_P the corresponding welfare losses.

If $\alpha_P = \alpha_L$ or $\alpha_P = 1$, subsidies in the bailout are unique and equal to s_L and s_0 , respectively. However, subsidies are not unique if $\alpha_L < \alpha_P < 1$: since the price impact depends only on the total

amount of liquidation, welfare depends only on the total subsidies awarded, but not on how those are distributed among banks. The regulator wishes to prevent any asset liquidation if $\alpha_P = 1$. It follows from (10) that this is the case if and only if $\lambda \leq \gamma \sum_{i=1}^n e^i$, i.e., if taxpayer contributions are considered cheap, if the asset price is sufficiently elastic, or if the total holdings in the illiquid asset exceed the threshold λ/γ . Depending on the distribution of the shortfall, the regulator may not be able to attain the indifference price in a complete bailout. Because the minimal required subsidies s_L induce asset price α_L , it is impossible to do so if $\alpha_{\text{ind}} < \alpha_L$. Note that the optimal complete bailout does not depend on the network structure because all defaults are prevented.

3.2 Credibility of the Regulator's Threat

If welfare losses in the public bailout of Lemma 3.2 are lower than in a default cascade, banks know that the regulator's preferred outside option is a bailout. The regulator thus has no credible threats to punish recalcitrant banks and, as a consequence, banks have no incentive to participate in any bail-in the regulator proposes. The following proposition shows that in such a situation, the regulator has no choice but to resort to a public bailout.

Proposition 3.3. *If $W_P < W_N$, the unique subgame Pareto efficient equilibrium outcome is the public bailout of Lemma 3.2.*

We say that the regulator's no-intervention threat is credible if and only if $W_N \leq W_P$. We will show in the following three subsections that when the threat is credible, the regulator can indeed incentivize banks to participate in a bail-in. In the remainder of this section, we study the conditions under which the threat is credible.²⁰

The main component of welfare losses in a bailout is the banks' aggregate shortfall $\sum_{i=1}^n s_0^i$, where s_0 is defined in (8). The aggregate shortfall is a measure of the size of the initial shock hitting the financial system, when the shock is large enough that banks can no longer pay their liabilities out of current income. Welfare losses in a default cascade are a measure of the size of the shock after it propagates through the financial system. Losses of junior creditors in a default cascaded are

$$S_N := \sum_{i=1}^n (V^i(L, 1) - V^i(p_N, \alpha_N))$$

The following result states that the regulator's threat is credible if and only if the amplification of losses through the financial system in absence of intervention is smaller than a certain threshold. Because senior creditors may absorb a portion of the losses, the part of the initial shock that is amplified through the network is

$$S_0 := \sum_{i=1}^n s_0^i - \sum_{i \in \mathcal{D}(p_N, \ell_N, \alpha_N)} \delta^i(p_N, \alpha_N).$$

²⁰Note that the credibility of the threat is a function of exogenous variables: the welfare losses W_P in the optimal bailout is the result of a minimization problem solved by the regulator alone and W_N are the welfare losses in absence of any action.

Lemma 3.4. *The regulator’s threat is credible if and only if*

$$S_N - S_0 \leq \lambda S_0 + \sum_{i=1}^n (e^i - s_0^i)^+ + g(\alpha_P). \quad (12)$$

The credibility threshold depends on the weight λ given to taxpayer contributions in the social welfare function, the size of the initial shortfall, and the distribution of the initial shortfall via the second and third term on the right-hand side of (12). The second term is a measure of the amount of illiquid assets that can be used to absorb the initial shock: if a larger part can be absorbed by the system, the threat is more credible. The last term in (12) captures the trade-off between liquidation costs and taxpayer contributions in the optimal bailout for a given distribution of shocks s_0 . While this trade-off is minimized at the indifference price α_{ind} , the regulator may not be able to attain α_{ind} for any distribution of shocks s_0 as seen in Lemma 3.2. The difference $g(\alpha_P) - g(\alpha_{\text{ind}})$ is thus a measure for how close to attaining α_{ind} the regulator can tailor a bailout for a given distribution of shocks; see also the discussion after Lemma 3.1.

Lemma 3.4 establishes a link between the credibility of the no-intervention threat and the existing literature on financial networks without intervention, which often ranks the desirability of network structures according to the welfare loss criterion $S_N - S_0$. Existing results in Allen and Gale (2000) and Acemoglu, Ozdaglar and Tahbaz-Salehi (2015) show that dense connections between banks may serve as an amplifier for large initial shocks. Since the right-hand side of (12) does not depend on the network structure, Lemma 3.4 indicates that dense connections are detrimental to the credibility of the threat when the initial shock is large.

3.3 Regulator’s Response in the Last Stage

It follows as a consequence to Lemma 3.2 that, for a given bail-in proposal (b, s) and the banks’ response vector a , the regulator’s best response in stage 3 is

$$r(b, s, a) = \begin{cases} \text{“no intervention”} & \text{if } W_N \leq \min(W_\lambda(b, s, a), W_P), \\ \text{“bailout”} & \text{if } W_P < \min(W_N, W_\lambda(b, s, a)), \\ \text{“bail-in”} & \text{otherwise.} \end{cases} \quad (13)$$

The regulator chooses the action that minimizes welfare losses if such an action is unique. Ties are broken according to “no intervention” \succ “bail-in” \succ “bailout” so that (a) taxpayer money is used only if it is strictly welfare increasing and (b) unilateral deviations by banks in stage 2 can be discouraged when $W_N = W_\lambda(b, s, a)$; see Lemma 3.5 and Footnote 21 below for details.

3.4 Banks’ Equilibrium Responses

In this section, we analyze how the banks respond to a given proposal when the regulator’s threat is credible. A crucial separation among the banks’ responses is whether or not they trigger the regulator’s decision to proceed with the bail-in.

Definition 3.1. Given a bail-in proposal (b, s) , an equilibrium response a is an *accepting equilibrium* if $r(b, s, a) = \text{“bail-in”}$ and it is a *rejecting equilibrium* otherwise.

Remark 3.1. The banks’ responses do not have to be unanimous in an accepting or rejecting equilibrium. Some banks may reject the proposal in an accepting equilibrium and vice versa. However, a sufficient proportion of banks accepts the proposal in an accepting equilibrium for the regulator to proceed with the bail-in.

For a bank to participate in a bail-in, the bail-in has to be incentive-compatible. Proposition 3.3 shows that when the regulator’s threat fails to be credible, the regulator can do no better than resorting to the public bailout of Lemma 3.2. If the threat is credible, the incentive-compatibility conditions are stated in the following lemma.

Lemma 3.5. *Suppose that $W_N \leq W_P$. Let (b, s) be a feasible proposal of a complete bail-in. In any accepting equilibrium a , bank i with $b^i > 0$ accepts if and only if:*

1. $W_\lambda(b, s, (0, a^{-i})) \geq W_N$, and
2. $b^i - s^i \leq \sum_{j=1}^n \pi^{ij} (L^j - p_N^j) + (\alpha(b, s, (1, a^{-i})) - \alpha_N) e^i$.

The first condition states that there is no possibility for free-riding: if bank i were to reject the proposal, the regulator would not make up for i ’s contribution and he would let a default cascade occur instead.²¹ In other words, the set of banks which accept the proposal is minimal in any accepting equilibrium. The second condition states how much bank i is willing to contribute to prevent a default cascade. Bank i is willing to make a net contribution up to the sum of its exposure to the default cascade through both channels of contagion.

Accepting equilibria need not be unique: for a given proposal, the regulator may be happy to organize a bail-in with more than one accepting coalition of banks. This raises the questions of how banks coordinate among different equilibrium responses. The following result shows that the regulator can preempt any problems of coordination by altering the proposed bail-in so that it is incentive compatible only for one consortium of banks to accept the proposal. If the regulator requests 0 contributions from any bank outside the selected consortium, unanimous acceptance becomes the unique accepting equilibrium of the revised proposal.

Lemma 3.6. *Let (b, s) be a bail-in with accepting equilibria $\{a_1, \dots, a_m\}$. For any $k = 1, \dots, m$, there exists a proposal (\tilde{b}, \tilde{s}) with $W_\lambda(b, s, a_k) = W_\lambda(\tilde{b}, \tilde{s}, 1)$, to which $1 = (1, \dots, 1)$ is the unique accepting equilibrium response.*

Our next result shows the banks will not reject a proposal if there is a subgame Pareto efficient equilibrium outcome in which the bail-in is implemented.

Lemma 3.7. *Suppose that a proposal (b, s) admits at least one accepting equilibrium. Then the accepting equilibrium leading to the lowest welfare losses is subgame Pareto efficient. Moreover, a rejecting equilibrium is subgame Pareto efficient if and only if (b, s) is the bailout given by Lemma 3.2.*

²¹The regulator prefers “no intervention” over “bail-in” in (13) when they lead to the same welfare losses so that a rejection by bank i can be prevented when $W_\lambda(b, s, (0, a^{-i})) = W_N$.

If a proposal admits a unique accepting equilibrium, its acceptance is the unique subgame Pareto efficient continuation by Lemma 3.7. For such a proposal, the regulator can anticipate the banks' responses and what the resulting welfare losses will be. It is thus suboptimal for the regulator to make a proposal that admits more than one accepting equilibrium: according to Lemma 3.6, the regulator could have revised his proposal to select his preferred response unambiguously. Among those proposals that admit only one accepting equilibrium, the regulator will thus propose the bail-in that minimizes welfare losses, subject to the incentive-compatibility conditions of Lemma 3.5. This is described in the following section.

3.5 Optimal Proposal of the Regulator

Contributions of banks to a bail-in affect welfare in two ways. First, they reduce the amount of taxpayer contributions needed. Second, if the asset price in the optimal bailout is larger than the indifference price, the regulator can use the contributions of banks to enhance welfare by exploiting the trade-off between asset liquidation and taxpayer contributions.

Lemma 3.8. *Let g and s_0 be defined as in Lemma 3.1 and (8), respectively, and let $b_0 := (c + \pi L - w - L)^+$. Let (b, s) be a complete feasible bail-in proposal with $b^i s^i = 0$ for every bank i .²² For any response vector a , welfare losses are equal to*

$$W_\lambda(b, s, a) = W_P + (g(\bar{\alpha}(b, s, a)) - g(\alpha_P)) + \lambda \sum_{i=1}^n (s^i - s_0^i)^+ - \lambda \sum_{i=1}^n \min(b^i, b_0^i) 1_{\{a^i=1\}}. \quad (14)$$

Equation (14) shows how welfare losses in a bail-in compare to welfare losses in the optimal bailout of Lemma 3.2. A contribution of bank i up to the amount b_0^i does not require asset liquidation, hence it does not impact the asset price. Thus, each dollar contributed up to b_0^i improves welfare by λ . Contributions in excess of b_0^i require asset liquidation by the bank, thereby impacting the asset price and the welfare trade-off g . Finally, subsidies beyond s_0 do not bring any benefit in terms of reduced fire-sale losses because banks can fulfill all obligations without liquidating assets. Each dollar of subsidies awarded in excess of s_0 thus effectively *burns* λ units of welfare. While this generally constitutes a decrease in welfare, we illustrate below how welfare burning can be used by the regulator to deter banks from free-riding.

Next, we analyze how the regulator best implements a rescue plan that satisfies the incentive-compatibility conditions of Lemma 3.5. The no-free-riding constraint in Condition 1 requires that after the rejection by any bank, welfare losses in the residual bail-in are larger than welfare losses in a default cascade. Using (14), this is equivalent to requiring that for any participating bank i ,

$$W_\lambda(b, s, a) \geq W_N + g(\bar{\alpha}(b, s, a)) - g(\bar{\alpha}(b, s, (0, a^{-i}))) - \lambda \min(b^i, b_0^i). \quad (15)$$

Equation (15) constitutes a lower bound on attainable welfare losses imposed by the no free-riding

²²The restriction $b^i s^i = 0$ imposes that bank i either receives subsidies or makes contributions to the bail-in, but not both. We show in Lemma C.1 in the appendix that this comes without loss of generality.

constraint. It states that welfare losses in an incentive-compatible bail-in cannot be lowered from W_N by more than the welfare impact stemming from the contribution of any participating bank.

The no-free-riding constraint thus drives the regulator to include in the bail-in banks which have a potential for large contributions or banks whose contributions enhance the welfare trade-off between subsidies and asset liquidation. It follows from Condition 2 in Lemma 3.5 that for a given set of liquidation decisions ℓ that induces asset price α , the vector of largest incentive-compatible contributions is

$$\eta(\alpha, \ell) := \min(\pi(L - p_N) + (\alpha - \alpha_N)e, (c + \alpha\ell + \pi L - w - L)^+). \quad (16)$$

The right expression in the minimum appearing in (16) is the vector of budget constraints in a bail-in, in which the banks' contributions induce the amount ℓ of asset liquidation.²³ Note that by choosing an incentive-compatible proposal (b, s) , the regulator implicitly chooses an associated vector of liquidation decisions $\ell(b, s, 1)$.²⁴ In order to construct a bail-in with maximal contributions by the banks, the regulator can thus choose ℓ first and propose a bail-in with contributions $\eta(\alpha(\ell), \ell)$. For a chosen set of liquidation decisions ℓ that induce asset price α , the necessary subsidies to guarantee solvency of every bank are

$$s(\alpha, \ell) := (L + w - c - \alpha\ell - \pi L)^+. \quad (17)$$

We say that a bail-in is individually incentive compatible if Condition 2 of Lemma 3.5 is satisfied for each bank when every bank accepts the regulator's proposal. The following lemma states that bail-ins of the above form are welfare-maximizing among individually incentive-compatible bail-ins.²⁵

Lemma 3.9. *Let (b, s) be a complete feasible bail-in that satisfies Condition 2 of Lemma 3.5 for every bank in the response vector $\mathbf{1} = (1, \dots, 1)$. Let $\mathcal{C} := \{i \mid b^i > 0\}$ and denote $\alpha = \bar{\alpha}(b, s, 1)$. Then*

$$W_\lambda(b, s, 1) \geq W_P - g(\alpha_P) + g(\alpha) - \lambda \sum_{i \in \mathcal{C}} \eta^i(\alpha, 0). \quad (18)$$

Equality holds in (18) if and only if $b^i - s^i \geq \eta^i(\alpha, 0)$ for every $i \in \mathcal{C}$ and $s^i \leq s_0^i$ for every $i \notin \mathcal{C}$.

Equation (18) shows that when contributions are of size $\eta(\alpha, \ell)$, their welfare impact depends on the liquidation decision only through the induced asset price. Thus, similarly to the bailout, the regulator optimizes bail-ins to induce the asset price, at which he is indifferent between additional taxpayer contributions and asset liquidation. Since banks are willing to make larger contributions to a bail-in that guarantees a higher asset price by Lemma 3.5, the regulator's indifference price in a bail-in is higher than in a bailout.

²³The model could easily be adapted to allow for capital requirements of solvent banks by subtracting the capital requirements from the budget constraint in the right expression of (16).

²⁴By Lemma 3.6, the regulator can aim to construct bail-ins that can be accepted by all banks without loss of generality.

²⁵Feasibility and individual incentive compatibility imply that $b^i - s^i \leq \eta^i(\alpha, e)$ for any contributing bank i . Since every bank is rescued in a complete bail-in, subsidies satisfy $s^i \geq s^i(\alpha, e)$ for every $i \notin \mathcal{C}$. The lower bound in (18) is thus attained if and only if $\eta^i(\alpha, 0) \leq b^i - s^i \leq \eta^i(\alpha, e)$ for any $i \in \mathcal{C}$ and $s^i(\alpha, e) \leq s^i \leq s^i(\alpha, 0) = s_0^i$ for any $i \notin \mathcal{C}$.

Suppose now that for a bail-in of the above form, some bank $i \in \mathcal{C}$ has an incentive to free-ride, that is, the regulator proceeds with the residual bail-in even without i 's participation. By Condition 1 in Lemma 3.5, this occurs precisely if $W_N - W_\lambda(b, s, (0, a^{-i})) \geq 0$. If the regulator were able to decrease welfare in the proposed bail-in by this amount for all response vectors, he could eliminate i 's free-riding incentives. It follows from Lemmas 3.8 and 3.9 that welfare in an individually incentive-compatible bail-in (b, s) with contributing banks in \mathcal{C} exceeds the lower bound in (18) by

$$\lambda \sum_{i \notin \mathcal{C}} (s^i - s_0^i)^+ + \lambda \sum_{i \in \mathcal{C}} (\eta^i(\alpha, 0) - b^i)^+. \quad (19)$$

Thus, providing subsidies in excess of s_0 and requesting contributions below $\eta(\alpha, 0)$ are means with which the regulator can decrease or ‘‘burn’’ welfare. Since subsidies in excess of s_0 and contributions below $\eta(\alpha, 0)$ do not affect the asset price, burning welfare as in (19) does not distort incentives and hence decreases welfare by the same amount in any response vector of the banks. We denote by $\chi_{\mathcal{C}}(\alpha)$ the minimal amount of welfare-burning needed to eliminate free-riding incentives from an individually incentive-compatible bail-in with contributing banks \mathcal{C} that induces asset price α . The mathematical definition of $\chi_{\mathcal{C}}(\alpha)$ is somewhat convoluted and deferred to Lemma A.1. In Theorem E.3 of the online appendix, we show that welfare burning is used sparingly in equilibrium.

The analysis above brings us to the characterization of the equilibrium intervention plan. The result states that when the threat is credible, the regulator proposes a bail-in which implements the minimum value burning $\chi_{\mathcal{C}}(\alpha)$ for the optimal choice of \mathcal{C} and α . For the sake of reference, we isolate the set of all incentive compatible bail-ins that implement the minimum value burning.

Definition 3.2. Let $z(\alpha) := \alpha \ln(\alpha)$ and let z^{-1} be its inverse on the interval $[\frac{1}{e}, 1]$. Define the function $g_\alpha(x) := g(z^{-1}(z(\alpha) + \gamma x)) - g(\alpha)$. Let $\Xi(\mathcal{C}, \alpha)$ denote the set of all bail-ins (b, s) satisfying:

- (i) $b^i - s^i \leq \eta^i(\alpha, e)$ for every $i \in \mathcal{C}$,
- (ii) $b^i = 0$ and $s^i(\alpha, e) \leq s^i$ for every $i \notin \mathcal{C}$,
- (iii) $\sum_{i=1}^n (s_0^i - s^i)^+ + \sum_{i \in \mathcal{C}} (b^i - b_0^i)^+ = -\frac{\alpha \ln(\alpha)}{\gamma}$,
- (iv) $\lambda \sum_{i=1}^n (s^i - s_0^i)^+ + \lambda \sum_{i \in \mathcal{C}} (\eta^i(\alpha, 0) - b^i)^+ = \chi_{\mathcal{C}}(\alpha)$,
- (v) $\lambda \min(b^i, b_0^i) + g_\alpha((b^i - b_0^i)^+) \geq W_N - W_P + g(\alpha_P) - g(\alpha) + \lambda \sum_{j \in \mathcal{C}} \eta^j(\alpha, 0) - \chi_{\mathcal{C}}(\alpha)$ for $i \in \mathcal{C}$.

The contribution of a bank $i \in \mathcal{C}$ to a bail-in affects welfare in two ways. Contributions up to $\eta^i(\alpha, 0)$ do not require asset liquidation and increase welfare by an amount $\lambda \eta^i(\alpha, 0)$. Contributions that exceed $\eta^i(\alpha, 0)$ by an amount x^i require asset liquidation and impact the welfare trade-off between taxpayer contributions and asset liquidation by an amount $g_\alpha(x^i)$. A contribution of size $\eta^i(\alpha, 0) + x^i$ by bank i thus has a total impact on welfare of $\lambda \eta^i(\alpha, 0) + g_\alpha(x^i)$. The first two Conditions in Definition 3.2 state that (b, s) is a feasible, complete bail-in with contributing banks in \mathcal{C} . Conditions (iii) and (iv) state that the bail-in induces asset price α and the total amount of welfare burnt is $\chi_{\mathcal{C}}(\alpha)$. Finally, Condition (v) states that there is no free-riding because the

welfare impact of any bank i (left hand side) is larger than the difference between the welfare losses in a default cascade and in the bail-in. Thus, Conditions (i) and (v) together imply that it is incentive-compatible for any bank $i \in \mathcal{C}$ to accept the proposal.

Theorem 3.10. *For any bail-in (b, s) , let $\ell(b, s)$ denote the vector of liquidated assets if the proposal is accepted by all banks. For any ℓ , let $i_1(\ell), i_2(\ell), \dots$ denote a decreasing order of banks according to $\eta^i(\alpha(\ell), \ell)$. Let $\mathcal{C}(\ell) := \{i_1(\ell), \dots, i_{m(\ell)}(\ell)\}$, where $m(\ell)$ denotes the smallest integer k such that*

$$W_P + (g(\alpha(\ell)) - g(\alpha_P)) - \lambda \sum_{j=1}^k \eta^{i_j(\ell)}(\alpha(\ell), \ell) < W_N.$$

If $W_P < W_N$, then any subgame Pareto efficient equilibrium outcome is a public bailout with welfare losses W_P as specified by Lemma 3.2. If $W_P \geq W_N$, then there exist generically unique \mathcal{C}_ and α_* such that in any subgame Pareto efficient equilibrium, a bail-in from the set $\Xi(\mathcal{C}_*, \alpha_*)$ is proposed by the regulator and accepted by all banks.²⁶ Welfare losses are equal to*

$$W_E = W_P + (g(\alpha_*) - g(\alpha_P)) - \lambda \sum_{i \in \mathcal{C}_*} \eta^i(\alpha_*, 0) + \chi_{\mathcal{C}_*}(\alpha_*).$$

Finally, if \mathcal{C}_ is unique, then $\mathcal{C}_* = \mathcal{C}(\ell(b, s))$ for all $(b, s) \in \Xi(\mathcal{C}_*, \alpha_*)$.*

As we have highlighted before, a bail-in can be organized in equilibrium if and only if the regulator's no-intervention threat is credible. The set of contributing banks \mathcal{C}_* is the set of banks that are most exposed to contagion at the equilibrium asset price α_* : after choosing a set of liquidation decisions ℓ that induces α_* , the regulator adds banks into the bail-in consortium in decreasing order of their incentive compatible contributions $\eta(\alpha(\ell), \ell)$ until welfare losses in the bail-in are lower than in the default cascade. This occurs after adding the $m(\ell)$ most exposed banks. Because of the no-free-riding constraint of Lemma 3.5, no more contributors can be added after that: any additional bank would know that even without its contribution, the regulator will proceed with the residual consortium and, hence, that bank has no incentive to participate.

The asset price and the welfare losses are generically unique in equilibrium. The set of liquidation decisions and the bail-in proposal, however, are not unique in general. Similarly as in the public bailout, welfare depends on the liquidation by banks only through the total amount that is being liquidated. This gives the regulator some leeway on how to induce asset price α_* . The only restriction on liquidation by an individual bank is the fifth condition in Definition 3.2, specifying the minimal liquidation amount by bank i for the no-free-riding condition to hold.

In Appendix E we highlight the relationship between the equilibrium asset price and the amount of welfare burnt in equilibrium: in many situations, the regulator will avoid burning welfare in equilibrium and instead choose to induce an asset price, at which the contributions by individual banks are sufficiently large to deter free-riding without burning welfare.

²⁶Generically unique means that it is unique for an open and dense set of model parameters.

Remark 3.2.

1. Banks are willing to make larger contributions to a bail-in that guarantees a higher asset price, hence the regulator's indifference price increases as more banks are included into the bail-in consortium. In particular, $\alpha_* \geq \min(\alpha_{\text{ind}}, 1)$.
2. If the regulator had the power to commit to not intervening in the third stage, the equilibrium outcome would improve to W_E even if $W_P < W_N$. Commitment power would thus improve social welfare by $(W_P - W_E)1_{\{W_P < W_N\}}$.

4 Shocks, Asset Illiquidity, and Total Throughput

In this section, we analyze the dependence of equilibrium quantities including asset prices, awarded subsidies, credibility, and welfare losses on the banks' balance sheet parameters, the network structure, and the recovery rates from asset liquidation and bankruptcy procedures.²⁷

4.1 Optimal Bailout

Since every bank is rescued in a complete bailout, there are no bankruptcy costs and no losses that depend on the network structure. Asset prices, subsidies, and welfare losses in the complete bailout are thus independent of β and π . The dependence of the welfare-maximizing bailout on the price elasticity γ , the welfare cost λ of a taxpayer dollar, and the size s_0 of the banks' shortfall is described in the following result and illustrated graphically in Figure 2.

Lemma 4.1. *There exist constants $0 < \gamma_1 < \gamma_2$ and $0 < \lambda_1 < \lambda_2$ such that:*

- (i) *The asset price α_P is decreasing for $\gamma \leq \gamma_1$, increasing for $\gamma \in [\gamma_1, \gamma_2]$, and equal to 1 for $\gamma \geq \gamma_2$. Subsidies and welfare losses are increasing for $\gamma \leq \gamma_2$ and constant for $\gamma \geq \gamma_2$.*
- (ii) *The asset price α_P and subsidies are constant for $\lambda \leq \lambda_1$, decreasing for $\lambda \in [\lambda_1, \lambda_2]$, and constant again for $\lambda \geq \lambda_2$. Welfare losses are increasing in λ .*
- (iii) *The asset price α_P is non-increasing in s_0^i for any bank i . Subsidies and welfare losses are increasing in s_0^i for any bank i .*

When the price elasticity γ is low, liquidation has a small impact on the asset price and it is welfare maximizing for the regulator to provide only the minimal amount of subsidies necessary to ensure solvency of all banks in the system. Under this minimal-intervention policy, the price of the asset falls as its elasticity increases. The resulting decrease of the banks' equity value requires larger subsidies to restore the system to a going concern. When the price elasticity rises above the threshold γ_1 , the regulator switches from the minimal-intervention policy to a policy that trades off

²⁷The results in this section are presented under the assumption that $\gamma > 0$, $e^i > 0$ for every bank i , and that there is at least one fundamentally defaulting bank. Without this assumption, the results in this section hold when strict monotonicity is replaced by weak monotonicity.

Figure 2: The three charts show the dependence of the optimal bailout on γ , λ , and e for a calibrated model of a dense financial network using the 2018 data of the EBA stress test.²⁸ The asset price $\alpha_P = \min(\max(\alpha_L, \alpha_{\text{ind}}), 1)$ is shown in solid blue lines; the minimal-intervention asset price α_L and the indifference price α_{ind} are shown in dashed blue lines. The total subsidies S_P awarded and welfare losses W_P are shown in yellow and red, respectively, normalized to fit the same scale. By Lemma 4.1, the dependence patterns are the same for arbitrary financial networks.

asset liquidation and taxpayer contributions to maintain the indifference price α_{ind} . As liquidation becomes more costly, the regulator has to provide additional subsidies to maintain the indifference price, which has a positive net effect on the asset price. In the interval $[\gamma_1, \gamma_2]$, non-defaulting banks thus benefit from additional market illiquidity—at the cost of taxpayer contributions—since their equity value increases with the asset price. Above the threshold γ_2 , liquidation is so costly that the regulator covers the banks’ entire shortfall s_0 to avoid any liquidation.

Covering the entire shortfall with taxpayer contributions is optimal if the welfare cost of taxpayer contributions is below the threshold λ_1 . Above the threshold, the regulator decreases the size of subsidies as λ increases to attain the indifference price. A decrease in subsidies will lead to a decrease in the asset price until, at level λ_2 , the regulator provides only the minimal subsidies necessary.

Finally, subsidies and welfare losses are increasing in the shortfall s_0 of the banks, which can be understood as a measure of the size of the initial shock. The asset price is strictly decreasing in the size of the shock where it exceeds the indifference price and it is constant otherwise. Since the indifference price does not depend on the size of the shock, a threshold where the transition takes place may not exist: the asset price may be strictly decreasing or it may be constant for any shock size.

Lemma 4.1 divides the space of parameters into regions where the regulator provides the minimal amount of subsidies ($\alpha_P = \alpha_L$), where the regulator trades off taxpayer contributions with asset liquidation ($\alpha_P = \alpha_{\text{ind}}$), and where liquidation is so costly that the regulator covers the entire shortfall with subsidies ($\alpha_P = 1$). To describe the same phenomenon in terms of the size of illiquid assets held by the banks, we need the notion of separating manifolds, which generalizes thresholds to higher dimensions. Separating manifolds, like separating hyperplanes, divide \mathbb{R}_+^n monotonically into two regions, but they can accommodate a non-linear boundary.

Definition 4.1. A *separating manifold* \mathcal{X} is a subset of \mathbb{R}^n that admits a global parametrization f^i along every coordinate $i = 1, \dots, n$ such that for every $x \notin \mathcal{X}$, either $f^i(x^{-i}) > x^i$ for each $i = 1, \dots, n$ or $f^i(x^{-i}) < x^i$ for each $i = 1, \dots, n$. We write $x < \mathcal{X}$ if $x^i < f^i(x^{-i})$ for each i and we write $x \leq \mathcal{X}$ if $x < \mathcal{X}$ or $x \in \mathcal{X}$. We define $>$ and \geq analogously.

²⁸Unlike the data calibration procedure for Section 6 described in Appendix D, we do not shut down the price-mediated contagion channel for Figures 2 and 4. Instead, we set 90% of outside assets reported by banks as illiquid and 10% as cash.

Lemma 4.2. *There exist separating manifolds $0 < \mathcal{E}_0 \leq \mathcal{E}_1 < \mathcal{E}_2$ such that:*

- (i) *For a fundamentally defaulting bank $i \in \mathcal{F}$, the asset price α_P and subsidies are decreasing in e^i for $e \leq \mathcal{E}_1$, increasing in e^i for $\mathcal{E}_1 \leq e \leq \mathcal{E}_2$, and constant for $e \geq \mathcal{E}_2$. Welfare losses are decreasing in e^i for $e \leq \mathcal{E}_0$, increasing in e^i for $\mathcal{E}_0 \leq e \leq \mathcal{E}_1$, and constant for $e^i \geq \mathcal{E}_2$.*
- (ii) *For a non-fundamentally defaulting bank $i \notin \mathcal{F}$, the asset price α_P and subsidies are constant in e^i for $e \leq \mathcal{E}_1$ or $e \geq \mathcal{E}_2$ and they are increasing in e^i for $\mathcal{E}_1 \leq e \leq \mathcal{E}_2$. Welfare losses are increasing in e^i for $e \leq \mathcal{E}_2$ and constant for $e^i \geq \mathcal{E}_2$.*

Similarly to Lemma 4.1, Lemma 4.2 divides the vector of illiquid asset holdings e into three regions, where it is optimal for the regulator to provide minimal assistance ($e \leq \mathcal{E}_1$), where the regulator trades off taxpayer contributions with asset liquidation ($\mathcal{E}_1 \leq e \leq \mathcal{E}_2$), and where the regulator prevents all liquidation ($e \geq \mathcal{E}_2$). Generally speaking, an increase in the sum of illiquid assets held by the entire system has a similar impact on the optimal bailout as an increase in the price elasticity because the same amount of liquidation leads to larger fire-sale losses. However, there is a subtle difference below \mathcal{E}_1 , where minimal subsidies are optimal: A fundamentally defaulting bank i cannot cover its shortfall by liquidating its assets. The regulator is thus forced to cover a large portion of the shortfall even if the marginal welfare cost of taxpayer contributions is higher than the marginal welfare impact of asset liquidation. As e^i increases, bank i is able to cover a larger portion of its shortfall by liquidating its assets, which reduces the size of the minimal subsidies required. Below the threshold \mathcal{E}_0 , the benefits of the reduced size of subsidies outweighs additional losses from fire sales, leading to an overall decrease in welfare losses. Note that \mathcal{E}_0 may be strictly lower than \mathcal{E}_1 if the aggregate amount of the illiquid asset held by the other banks in the system is large. See the right panel in Figure 2 for a graphical illustration.

4.2 Credibility

For a given set of parameters, the threat is either credible or not. To analyze how the credibility depends on underlying variables, we study the difference $W_P - W_N$ between the welfare losses in the optimal bailout and the default cascade. This measures how close to being credible the threat is. We say that the credibility of the threat is increasing or decreasing in a parameter if $W_P - W_N$ is, respectively, increasing and decreasing in that parameter.

A critical measure for the sensitivity analysis is the *total throughput* of a defaulting bank to the solvent members of the economy. We define it as follows. Abbreviate $\mathcal{D}_N = \mathcal{D}(p_N, \ell_N, \alpha_N)$, let $\mathcal{C}_N \subseteq \mathcal{D}_N$ denote the set of defaulting banks which repay their senior creditors in full, and let \mathcal{I}_N denote the set of illiquid but solvent banks. For two sets of banks \mathcal{S} and \mathcal{C} , let $\pi^{\mathcal{S}, \mathcal{C}}$ denote the submatrix of π with rows and columns corresponding to banks in \mathcal{S} and \mathcal{C} , respectively. The *throughput* of a bank $i \in \mathcal{C}_N$ to a set of banks \mathcal{S} is

$$\theta_{\mathcal{S}}^i(\beta, \pi) := \sum_{j \in \mathcal{S} \setminus \mathcal{D}_N} \pi^{\{j\} \mathcal{C}_N} (I - \beta \pi^{\mathcal{C}_N, \mathcal{C}_N})^{-1} \rho_i^{\mathcal{C}_N} + \beta \sum_{j \in \mathcal{S} \cap \mathcal{D}_N \setminus \mathcal{C}_N} \pi^{\{j\} \mathcal{C}_N} (I - \beta \pi^{\mathcal{C}_N, \mathcal{C}_N})^{-1} \rho_i^{\mathcal{C}_N}. \quad (20)$$

Figure 3: Let π_c and π_r denote the complete and the ring network, respectively. The two charts show the total throughput $\theta^1(\beta, \pi_\mu)$ of bank 1 in the network $\pi_\mu = \mu\pi_c + (1 - \mu)\pi_r$ for various levels of β , when $\mathcal{C}_N = \mathcal{D}_N = \{1, 2\}$ and $\mathcal{C}_N = \mathcal{D}_N = \{1, 2, 3, 4, 5\}$ in the left and right panel, respectively.

where $\rho_i^{\mathcal{C}_N}$ denotes the unit vector in $\mathbb{R}^{\mathcal{C}_N}$ in the direction of i . The *total throughput* of bank $i \in \mathcal{C}_N$ is then defined as $\theta^i(\beta, \pi) := \theta_{\{1, \dots, N\}}^i(\beta, \pi)$. For a bank $i \in \mathcal{D}_N \setminus \mathcal{C}_N$, we set $\theta^i(\beta, \pi) := 1$.

The total throughput of bank i is a measure of the exposure of solvent junior creditors (first term) and senior creditors (second term) to a shock hitting bank i . It thus quantifies the potential for spill-over losses triggered by defaults. For a bank $i \in \mathcal{C}_N$, it captures the amplification of losses due to negative feedback loops between defaulting banks through the Leontief matrix $(I - \beta\pi^{\mathcal{C}_N, \mathcal{C}_N})^{-1} = \sum_{k=0}^{\infty} (\beta\pi^{\mathcal{C}_N, \mathcal{C}_N})^k$: term k in the sum corresponds to the propagation of losses through liability chains in \mathcal{C}_N of length k . After accounting for feedback effects and bankruptcy losses, the exposure of a solvent creditor to a shock on bank i 's assets is π^{ji} for a solvent bank j and $\beta\pi^{ji}$ for the senior creditors of a bank $j \in \mathcal{D}_N \setminus \mathcal{C}_N$.²⁹ The total throughput is a normalized measure for the rate of spill-over losses that condenses all the network information needed to determine the credibility of the regulator's threat, as specified by the following lemma.

Lemma 4.3. *The total throughput of any bank is non-decreasing in β and it takes values in $[0, 1]$. Conditional on the banks' levels of solvency (the sets \mathcal{D}_N , \mathcal{C}_N , and \mathcal{I}_N) and the total value of their claims on solvent banks, $W_P - W_N$ depends on π only through $\sum_{i \in \mathcal{C}_N} \theta_{\mathcal{I}_N}^i(\beta, \pi)$ and $\sum_{i \in \mathcal{C}_N} \theta^i(\beta, \pi)$.*

Observe from (20) that the throughput depends only on the network structure, the location of the shocked bank(s) within the network, the connections of the shocked banks to other defaulting banks, as well as the recovery rate β . Conditional on the banks' levels of solvency, it does not, however, depend on the asset price or the banks' balance sheet quantities L , c , w , and e . The throughput is increasing in the connectivity between defaulting banks as illustrated in Figure 3.³⁰ We are now ready to determine the dependency of the credibility on the model parameters.

Lemma 4.4.

(i) *The credibility of the threat is increasing in λ .*

²⁹The total throughput of bank $i \in \mathcal{C}_N$ is related to the bank's Bonacich centrality $B^i = \mathbf{1}_{\mathcal{C}_N}^\top (I - \beta\pi^{\mathcal{C}_N, \mathcal{C}_N})^{-1} \rho_i^{\mathcal{C}_N}$, which captures the total amplification of losses through feedback loops in \mathcal{C}_N . The total throughput additionally takes into account how the losses are distributed among the creditors. It is important to note that the Bonacich centrality may diverge to ∞ if $\beta \rightarrow 1$, whereas our notion of total throughput is bounded on the interval $[0, 1]$.

³⁰The symmetric complete network π_c with $\pi_c^{ij} = 1_{\{i \neq j\}} / (n-1)$ is the least concentrated network structure. The ring network π_r with $\pi_r^{ij} = 1_{\{j=i+1 \pmod n\}}$ is the sparsest network structure as measured by the Gini index; see Hurley and Rickard (2009).

Figure 4: The three charts show the dependence of the optimal bailout on γ , β , and e for a calibrated model of a dense financial network using the 2018 data of the EBA stress test. In the right chart, we scale the size of illiquid assets held by all banks simultaneously, leading to a cluster of thresholds e_*^i , where each bank i becomes solvent and the credibility of the threat increases.

- (ii) *The credibility of the threat is non-decreasing in β and it is strictly increasing on the set $\{\beta \mid \text{there exists } i \in \mathcal{D}_N(\beta) \text{ with } \theta^i(\beta, \theta) > 0\}$.*
- (iii) *The credibility of the threat is decreasing in γ for $\gamma \geq \gamma_2$. For $\gamma \leq \gamma_2$, an increase in γ leads to downward discontinuities in $W_P - W_N$ when additional banks default. The marginal change of $W_P - W_N$ at continuity points in $[0, \gamma_2]$ is decreasing in β and $\theta^i(\beta, \pi)$ for every defaulting bank i ; see Lemma H.14 in the online appendix for the precise expression.*
- (iv) *If $(1 + \lambda)\beta \leq 1$ or $\mathcal{D}_N = \mathcal{C}_N$, then for each i and fixed e^{-i} , there exists e_*^i such that the credibility of the threat is decreasing in e^i everywhere except at e_*^i where $W_P - W_N$ has an upward discontinuity.³¹*

As the welfare cost λ of taxpayer contribution increases, a bailout becomes more costly and the threat becomes more credible. Similarly, as the recovery rate β increases, bankruptcies become less costly and it becomes more credible that the regulator will not intervene. If the throughput of all defaulting banks is 0, then losses generated by defaulting banks do not spill over to the rest of the system, hence welfare losses are locally constant in β .³² However, if the set of defaulting banks is connected to the rest of the system, then the credibility is strictly increasing in β .

As the price elasticity γ increases, liquidation has a larger knock-down effect on the asset's price. Illiquid banks are able to raise a smaller amount of cash from their sales and, when γ crosses a certain threshold, are unable to meet their liabilities. In the absence of intervention, the set of defaulting banks increases at such a threshold of asset illiquidity, causing a downward discontinuity in the credibility of the threat due to bankruptcy losses. Between these discontinuities, two counteracting forces determine the change in credibility: a larger impact on the asset price causes larger liquidation losses in the absence of intervention but also mandates larger subsidies in a bailout. Which effect dominates depends on the recovery rate β and the network structure via the total throughput of defaulting banks. As illustrated in Figure 3, the marginal change in credibility is higher in more sparsely connected networks. As seen in the left panel of Figure 4, the discontinuities typically

³¹If $(1 + \lambda)\beta > 1$ and $\mathcal{D}_N \neq \mathcal{C}_N$, then one can give a similar condition on the marginal change of $W_P - W_N$ as in (iii).

³²Indeed, if all senior creditors are repaid in full and the defaulting banks are only liable to each other but not to the solvent banks in the system, then repayments are just a redistribution of net zero wealth among defaulting banks.

dominate the continuous changes in the credibility. When $\gamma \geq \gamma_2$, subsidies in the bailout are constant and the credibility decreases.

An increase in the amount of illiquid asset held by any bank increases the system's exposure to fire-sale losses both in the optimal bailout and in the default cascade. Because fire-sale losses are partially mitigated when a bailout is implemented, the sensitivity of welfare losses to higher asset holdings is stronger in absence of intervention than in a bailout. Therefore, the credibility of the threat is decreasing in e^i for each bank i except at the threshold e_*^i , where bank i changes from being insolvent for $e^i < e_*^i$ to being solvent for $e^i \geq e_*^i$; see the right panel in Figure 4.

The following result shows how the credibility of the threat changes with the size of the initial shock. For the credibility analysis, we write $c = c_0 - \varepsilon$ as the sum of cash kept in period $t = 0$ and the realization of short-term returns on the illiquid assets in period $t = 1$, where ε is interpreted as the size of the shock to those returns. In contrast, the public bailout depends on the size ε of the initial shock only through the shortfall s_0 , hence Lemma 4.1 simply states the dependency on s_0 .

Lemma 4.5. *For each bank i , there exist $0 < \varepsilon_1^i < \varepsilon_2^i \leq \varepsilon_3^i$ such that the credibility of the threat is constant for $\varepsilon^i \leq \varepsilon_1^i$, decreasing for $\varepsilon^i \in [\varepsilon_1^i, \varepsilon_2^i]$, and increasing for $\varepsilon^i \geq \varepsilon_3^i$. On the interval $[\varepsilon_2^i, \varepsilon_3^i]$, the credibility has only downward discontinuities. The marginal change of $W_P - W_N$ at continuity points in $[\varepsilon_2^i, \varepsilon_3^i]$ is decreasing in β and $\theta^i(\beta, \pi)$.*

For very small shock sizes, bank i is able to honor its liabilities without liquidating its assets. Welfare losses and the credibility of the threat thus remain unaffected. For small shock sizes in the interval $[\varepsilon_1^i, \varepsilon_2^i]$, bank i has to start liquidating its assets in absence of intervention, but not in the public bailout where all interbank claims are honored. The credibility of the threat is thus decreasing in that interval. For intermediate shock sizes in the region $[\varepsilon_2^i, \varepsilon_3^i]$, banks have insufficient liquidity to repay their liabilities both in the bailout and in the no-intervention outcome. Whether this leads to a larger increase of welfare losses without intervention than in a bailout—and hence to a decrease in credibility—depends on the recovery rate β , and the total throughput of bank i in the default cascade. Finally, for large shock sizes $\varepsilon^i \geq \varepsilon_3^i$, bank i does not make any payment to its junior creditors in the default cascade, hence any marginal increase in the shock is not amplified through the network anymore. Consequently, the credibility is increasing in the shock size.

We conclude this section with the following result, which highlights that the credibility of the threat is the most important determinant when comparing welfare losses between two networks.

Lemma 4.6. *For fixed $L, e, c, w, \gamma, \beta$, equilibrium welfare losses after intervention are smaller in network π_1 than in network π_2 if the regulator's threat is credible in π_1 but not in π_2 .*

Indeed, if the regulator's threat is credible in network π^1 but not in network π^2 , Theorem 3.10 implies that $W_E(\pi^1) < W_N(\pi^1) \leq W_P = W_E(\pi^2)$. If the threat fails to be credible in both networks, the only available option for the regulator in either network is a public bailout. Therefore, equilibrium welfare losses are identical in both networks. In Section 6, we compare welfare losses when the threat is credible in both networks. We do that numerically, using a data set from the European Banking Authority's 2018 stress test.

5 Optimal Intervention with Partial Rescues

In this section, we extend the baseline model of Section 3 by enlarging the strategy space of the government from complete rescues to bail-ins and bailouts that may rescue only a subset of the banks. We also refer to these interventions as partial interventions or partial rescues. This analysis reveals the additional forces that contribute to the formation of bail-ins when the regulator does not necessarily rescue every bank in the system. To simplify the analysis and the exposition of our results, we assume a perfectly elastic asset price, that is, we set $\gamma = 0$. This is equivalent to assuming that banks do not hold any illiquid asset and all non-interbank claims are cash assets.

5.1 Public Bailout

Without the participation of the banks, the regulator minimizes welfare losses over all possible sets of banks he could bail out. The first lemma describes this minimization procedure.

Lemma 5.1. *For any set of banks \mathcal{B} , let $p(\mathcal{B})$ be the greatest fixed-point of*

$$p^i = \begin{cases} L^i & \text{if } i \in \mathcal{B} \text{ or } c^i + \sum_{j=1}^n \pi^{ij} p^j \geq L^i + w^i, \\ \left(\beta(c^i + (\pi p)^i) - w^i \right)^+ & \text{otherwise.} \end{cases}$$

Define the vector of subsidies $s(\mathcal{B})$ by setting $s^i(\mathcal{B}) := (L^i + w^i - c^i - \sum_{j=1}^n \pi^{ij} p^j(\mathcal{B}))^+$ for $i \in \mathcal{B}$ and $s^i(\mathcal{B}) = 0$ otherwise. Let $\mathcal{B}_P := \arg \min_{\mathcal{B}} W_\lambda(s(\mathcal{B}))$. A welfare-maximizing partial bailout awards subsidies from the set $\mathcal{S}_P := \{s(\mathcal{B}_*) \mid \mathcal{B}_* \in \mathcal{B}_P\}$ and attains welfare losses $W_P^* := \min_{\mathcal{B}} W_\lambda(s(\mathcal{B}))$.

The bailout $s(\mathcal{B})$ is the welfare-maximizing bailout among all bailouts that rescue banks in \mathcal{B} by giving subsidies only to banks in \mathcal{B} . The regulator thus maximizes welfare by optimally selecting which banks to subsidize. Generically, \mathcal{B}_P is a singleton, that is, welfare is maximized for a unique set of banks to be bailed out. Note that in Lemma 5.1, we do not preclude the possibility that the optimal partial bailout rescues no banks at all. In that case, the optimal ‘‘bailout’’ is the default cascade. The following result describes the structure of the partial bailout by characterizing conditions under which it is optimal not to rescue a certain set of banks. Those conditions depend on the shortfall $S(\mathcal{B})$ and the capital buffer $C(\mathcal{B})$ in the bailout $s(\mathcal{B})$, defined as follows:

$$S(\mathcal{B}) := (L + w - c - \pi p(\mathcal{B}))^+, \quad C(\mathcal{B}) := (c + \pi p(\mathcal{B}) - w - L)^+. \quad (21)$$

For the sake of brevity, we set $\delta(\mathcal{B}) = \delta(p(\mathcal{B}))$ and $\mathcal{D}(\mathcal{B}) = \mathcal{D}(p(\mathcal{B}))$, and denote by $\mathcal{S}(\mathcal{B}) = \mathcal{D}(\mathcal{B})^c$ the set of solvent banks in the bailout $s(\mathcal{B})$, where A^c denotes the complement of the set A .

Lemma 5.2. *For any two sets of banks $\mathcal{B}, \mathcal{B}'$ such that $\mathcal{B}' \subseteq \mathcal{B}$, let $\zeta := \pi(p(\mathcal{B}) - p(\mathcal{B}'))$ and $\mathcal{R} := \mathcal{D}(\mathcal{B}') \setminus \mathcal{D}(\mathcal{B})$. Then $W_\lambda(\mathcal{B}') < W_\lambda(\mathcal{B})$ if and only if*

$$\sum_{i \in \mathcal{R}} S^i(\mathcal{B}') + \frac{\lambda}{1 + \lambda} \sum_{i \in \mathcal{S}(\mathcal{B})} \min(\zeta^i, C^i(\mathcal{B})) > \sum_{i \in \mathcal{R}} \delta^i(\mathcal{B}') + \sum_{i \in \mathcal{D}(\mathcal{B})} \min(\beta \zeta^i, \delta^i(\mathcal{B}')) + \sum_{i \in \mathcal{S}(\mathcal{B})} \zeta^i. \quad (22)$$

The left-hand side of (22) captures the benefits for not rescuing banks in \mathcal{R} . The first term is proportional to the shortfall of banks in \mathcal{R} if those banks are not rescued. Rescuing them is costly and requires government expenditures in the form of awarded subsidies. The second term captures the potential of solvent banks to absorb losses ζ caused by the default of banks in \mathcal{R} . If solvent banks have sufficiently large capital buffers, these losses can be absorbed by the system and there is less benefit in rescuing the defaulting banks using public money. The right-hand side of (22) captures the benefits of rescuing banks in \mathcal{R} . These include the direct benefits to senior creditors (first two terms) and solvent junior creditors (third term) if banks in \mathcal{R} are rescued. Benefits to insolvent banks do not explicitly appear in the expression above because those benefits are passed on to creditors of rescued banks through the repayment of liabilities.

Lemma 5.2 implies that a bank is not rescued in the optimal bailout if it is hit by a very large shock or if such a shock can be well-absorbed by the capital buffer of its creditors. By contrast, a bank is rescued in the optimal bailout if, relative to the size of the exogenous shock, the bank's default causes large losses to its creditors that cannot be absorbed by their capital buffers. Losses are particularly large if the bank's bankruptcy causes a default cascade. If a bank is hit by a large shock *and* its bankruptcy causes a default cascade, it may be welfare enhancing to rescue the contagiously defaulting banks as opposed to the fundamentally defaulting bank: To rescue the fundamentally defaulting bank, the regulator has to cover the bank's large shortfall entirely using taxpayer money. If he rescues only the contagiously defaulting banks, he can leverage the balance sheet capacity of those banks and cover the residual shortfall only after the capital buffers of the contagiously defaulting banks have been depleted.

From an ex-ante perspective, our result implies that a risky bank i has incentives to borrow from other risky banks in the system so that in case of i 's default, its creditors are likely to be distressed as well. Then, their potential for absorbing the losses induced by bank i is small, increasing the chances that bank i is bailed out. (As we noted in the introduction, in this paper we do not, however, pursue the ex-ante implications of our bail-out strategies.)

5.2 Banks' Equilibrium Responses

When the regulator commits to complete bailouts as in Section 3, the threat towards the banks is binary: a bank's assets are either fully protected or they are exposed to the full extent of the default cascade. This is no longer the case when the government allows for partial bailouts. A bank's assets may be protected to varying degrees in a welfare-maximizing bailout: while some debtors may be rescued and hence the claims towards those banks are protected, other debtors may still default, thereby inducing losses to the remaining banks in the system. Thus, banks may have an incentive to participate in a bail-in even if the regulator cannot credibly threaten a default cascade.

If there is more than one set of banks, whose bailout is welfare-maximizing, the regulator can choose which one to implement. If the regulator announces that he will implement the bailout $s(\mathcal{B})$ when banks fail to cooperate, he threatens to not rescue banks in \mathcal{B}^c . Because he can credibly implement any optimal bailout after any response vector by the banks, he can "threaten" different

bailouts to different banks. Consider a financial system with two identical defaulting banks i and j , where the welfare-maximizing bailout prescribes the rescue of only one of them. Since rescuing either is a credible action by the regulator, he can threaten the creditors of bank i that, without their participation, he will bail out bank j and vice versa. This is formalized in the following lemma.

Lemma 5.3. *Let (b, s) be a feasible bail-in proposal. In an accepting equilibrium a , bank i with $b^i > 0$ accepts if and only if for some $\mathcal{B}_i \in \mathcal{B}_P$, the following conditions hold:*

1. $W_\lambda(b, s, (0, a^{-i})) \geq W_P$,
2. $b^i - s^i \leq \sum_{j=1}^n \pi^{ij} (\bar{p}^j(b, s, (1, a^{-i})) - p^j(\mathcal{B}_i)) - s^i(\mathcal{B}_i)$.

Moreover, if there exists $\mathcal{B}_* \in \mathcal{B}_P$ such that Condition 2 holds simultaneously for every bank i with $\mathcal{B}_i = \mathcal{B}_*$, then rejecting equilibria are subgame Pareto efficient only if $s \in \mathcal{S}_P$. If there exists no such \mathcal{B}_* for any accepting equilibrium, then rejecting equilibria are not subgame Pareto dominated by accepting equilibria.

Condition 1 is analogous to that in the case of complete bailouts and states that a participating bank must not have an incentive to free-ride. Specifically, Condition 1 imposes that without i 's participation, the regulator chooses his preferred outside option over the residual bail-in.³³ Condition 2 states that bank i 's net contribution to the bail-in (b, s) has to be smaller than or equal to i 's benefits in the bail-in over the threatened bailout $s(\mathcal{B}_i)$. If bank i or i 's debtors are rescued in the bailout $s(\mathcal{B}_i)$, the benefits are lower and i has a lower incentive to contribute. If the optimal bailout of Lemma 5.1 is not unique, the regulator has some room to adjust the threats towards the banks by selecting \mathcal{B}_i accordingly. However, if the regulator threatens different bailouts after the rejection by individual banks, the threats can no longer be carried out against all banks simultaneously. Thus, at least one bank is not punished as harshly as it was threatened, hence that bank is strictly better off rejecting the proposal. As a consequence, rejecting equilibria are no longer Pareto dominated by accepting equilibria. The regulator can ensure that his proposal is accepted in equilibrium if he threatens the same bailout after any response from the banks.³⁴ This corresponds to a risk-averse regulator who minimizes welfare losses in the worst-case outcome over all subgame Pareto-efficient continuation equilibria.

5.3 Optimal Proposal of the Regulator

In a partial bail-in, the regulator selects both rescued banks and contributors. Because a bank is more willing to contribute to a bail-in that protects its debtors, the two decisions are interconnected.

³³Note that in the case of partial rescues, the preferred outside option is the threatened partial bailout $s(\mathcal{B}_i)$ leading to welfare losses W_P . By contrast, Lemma 3.5 for complete rescues is formulated under the assumption that the threat is credible, where the regulator's preferred outside option is the default cascade with welfare losses W_N .

³⁴The regulator can choose which welfare-maximizing bailout to implement after any response vector. If it is possible to assign bailouts to response vectors such that at least one bank has an incentive to deviate for any $a \neq (1, \dots, 1)$, the regulator can prevent the existence of rejecting equilibria. In that case, it does not matter that threats towards different banks cannot be carried out simultaneously. Whether or not rejecting equilibria can be prevented is a combinatorial argument that depends on the number of participating banks, the number of credible bailout threats, and the rank-order of the threats for the individual banks. Since the optimal bailout is generically unique in this framework, this analysis is beyond the scope of the paper.

When the regulator proposes to rescue a set of banks \mathcal{B} and threatens the bailout $s(\mathcal{B}_*)$, the maximal incentive-compatible contribution by bank i , or the *threat level* towards bank i , is equal to

$$\eta_{\mathcal{B}_*}(\mathcal{B}) := \min\left(\left(\pi(p(\mathcal{B}) - p(\mathcal{B}_*)) - s(\mathcal{B}_*)\right)^+, C(\mathcal{B})\right), \quad (23)$$

where $C(\mathcal{B})$ is the vector of the banks' capital buffer defined in (21). The notion of threat levels generalizes the credibility of the threat in Section 3.³⁵ If the optimal bailout happens to be the complete bailout, then threat levels towards all banks are zero and, as in Section 3, the regulator cannot incentivize any banks to participate. If the optimal bailout is not the complete bailout, the regulator minimizes welfare losses over which banks to subsidize, taking into account that it affects the contributions he can extract from the private sector. We state the result under the generically satisfied assumption that the optimal bailout is unique. If the welfare-maximizing bailout fails to be unique, the regulator will additionally optimize over which bailouts to threaten.

Theorem 5.4. *Suppose that $\mathcal{B}_P = \{\mathcal{B}_*\}$. For any set of banks \mathcal{B} , denote by $i_1(\mathcal{B}), i_2(\mathcal{B}), \dots$ a non-increasing ordering of banks according to $\eta_{\mathcal{B}_*}^i(\mathcal{B})$. For any integer k , define*

$$W^k(\mathcal{B}) := W_\lambda(s(\mathcal{B})) - \lambda \sum_{j=1}^k \eta_{\mathcal{B}_*}^{i_j(\mathcal{B})}(\mathcal{B}).$$

Let $m(\mathcal{B})$ denote the smallest k for which $W_{\mathcal{B}_*}^k(\mathcal{B}) < W_P$ and set

$$W(\mathcal{B}) = \min\left(W^{m(\mathcal{B})}(\mathcal{B}), W_P - \lambda \eta_{\mathcal{B}_*}^{i_{m(\mathcal{B})+1}(\mathcal{B})}(\mathcal{B})\right). \quad (24)$$

In the game with partial interventions, the welfare losses in any subgame Pareto-efficient equilibrium are equal to $W_E^* := \min_{\mathcal{B}} W(\mathcal{B})$.

As in Theorem 3.10, the no-free-riding constraint drives the regulator to ask for contributions from banks, towards which the threat level is the highest. He includes banks into the bail-in consortium according to the decreasing order $i_1(\mathcal{B}), i_2(\mathcal{B}), \dots$ until welfare losses are lower than in the default cascade (left expression in the minimum of (24)). After that, he can only include additional banks into the consortium by burning welfare (right expression in the minimum of (24)).³⁶

In addition to the above forces that also govern the formation of a complete bail-in, the selection of rescued banks affects the size of the contributions the regulator can demand from the private

³⁵Because rescues are required to be complete in Section 3, it follows that $\mathcal{B} = \{1, \dots, n\}$ and hence $p(\mathcal{B}) = L$. With complete rescues, the threat level towards the banks is thus either 0 (if the no-intervention threat fails to be credible and hence $p(\mathcal{B}_*) = L$) or it is given by $\eta(\alpha(\ell), \ell)$ in (16) for any bail-in that induces asset liquidation ℓ (if the no-intervention threat is credible and hence $p(\mathcal{B}_*) = p(\theta) = p_N$ and $s(\mathcal{B}_*) = 0$). Here, we highlight the dependence on the set \mathcal{B} of subsidized banks because $\ell = 0$ and $\alpha = 1$ in this section.

³⁶In absence of price-mediated contagion, the order $i_1(\mathcal{B}), i_2(\mathcal{B}), \dots$ of banks most exposed to contagion does not depend on the number of banks included in the consortium. The order is fixed for given \mathcal{B} and \mathcal{B}_* , and this simplifies the characterization of welfare burning in equilibrium: To include an additional bank i into the consortium, the regulator burns $W_P - W^{m(\mathcal{B})}(\mathcal{B})$ units of welfare so that without i 's participation, welfare in the residual bail-in and the optimal bailout are identical. Then, bank i does not have an incentive to free-ride. Because banks are decreasingly ordered according to their threat levels, the regulator will consider burning welfare only to include bank $i_{m(\mathcal{B})+1}(\mathcal{B})$.

sector. In equilibrium, the regulator will include few banks into the bail-in consortium, each willing to make a large contribution, rather than many banks with small contributions each. It is, therefore, beneficial to rescue banks which have few large creditors rather than banks with many small creditors. This is formalized in the following lemma. It characterizes the structure of partial equilibrium bail-ins by giving conditions, under which it is optimal not to rescue a certain set of banks. We use the same notation as in Lemma 5.2 and Theorem 5.4, and additionally denote by $\mathcal{C}(\mathcal{B}) := \{i_1(\mathcal{B}), \dots, i_{m(\mathcal{B})}(\mathcal{B})\}$ the set of contributing banks towards a rescue of banks in \mathcal{B} .

Lemma 5.5. *Suppose that $\mathcal{B}_P = \{\mathcal{B}_*\}$. For any two sets of banks $\mathcal{B}' \subseteq \mathcal{B}$, let $\mathcal{R} := \mathcal{D}(\mathcal{B}') \setminus \mathcal{D}(\mathcal{B})$ as in Lemma 5.2. Then $W_\lambda(s(\mathcal{B}')) - \sum_{i \in \mathcal{C}(\mathcal{B}')} \lambda \eta^i(\mathcal{B}') < W_\lambda(s(\mathcal{B})) - \sum_{i \in \mathcal{C}(\mathcal{B})} \lambda \eta^i(\mathcal{B})$ if and only if*

$$\begin{aligned} \sum_{i \in \mathcal{R}} S^i(\mathcal{B}') + \frac{\lambda}{1+\lambda} \sum_{i \in \mathcal{S}(\mathcal{B})} \min(\zeta^i, C^i(\mathcal{B})) + \frac{\lambda}{1+\lambda} \left(\sum_{i \in \mathcal{C}(\mathcal{B}')} \eta_{\mathcal{B}_*}^i(\mathcal{B}') - \sum_{i \in \mathcal{C}(\mathcal{B})} \eta_{\mathcal{B}_*}^i(\mathcal{B}') \right) \\ > \sum_{i \in \mathcal{R}} \delta^i(\mathcal{B}') + \sum_{i \in \mathcal{D}(\mathcal{B})} \min(\beta \zeta^i, \delta^i(\mathcal{B}')) + \sum_{i \in \mathcal{S}(\mathcal{B})} \zeta^i + \frac{\lambda}{1+\lambda} \sum_{i \in \mathcal{C}(\mathcal{B})} \min(\zeta^i, \eta_{\mathcal{B}_*}^i(\mathcal{B})). \end{aligned} \quad (25)$$

Similarly to the characterization of the optimal bailout in Lemma 5.2, the left-hand side of (25) represents the benefits of not rescuing banks in \mathcal{R} , whereas the right-hand side represents the benefits of rescuing banks in \mathcal{R} . The majority of terms are identical to (22), but there are two key differences. The first is related to the system's ability to absorb losses transmitted from banks in \mathcal{R} when they are not rescued (second term on the left-hand side of (25)). Losses are absorbed either partially or completely by the capital buffers of \mathcal{R} 's creditors. In order to benefit from those capital buffers in a partial bailout, the regulator has an incentive to let banks in \mathcal{R} default. In the bail-in, the regulator benefits from those capital buffers even when he rescues the banks in \mathcal{R} because he can extract larger contributions—up to the amount $\eta(\mathcal{B}) \leq C(\mathcal{B})$ —from contributors in $\mathcal{C}(\mathcal{B})$ (third term on the right-hand side of (25)). The choice of which banks to rescue is thus *network-dependent*: If banks in \mathcal{R} have many creditors, only some of them will be included in the consortium $\mathcal{C}(\mathcal{B})$ due to free-riding incentives. Thus, if capital buffers are large and the defaults of banks in \mathcal{R} can be well absorbed, the second term on the left-hand side of (25) is larger than the third term on the right-hand side, constituting a reason not to rescue banks in \mathcal{R} . If, however, \mathcal{R} has only a few large creditors, those are likely included in $\mathcal{C}(\mathcal{B})$ and hence the two terms balance out.³⁷ While, in the partial bailout, only the size of the absorbed losses matter, in the partial bail-in the distribution of those losses matters as well because it determines the contributions that can be elicited from the private sector.

The second difference from the case of complete bailouts is the third term on the left-hand side of (25). It captures the structure of rescue consortia in the two alternative bail-ins, stating that it is beneficial to not rescue banks in \mathcal{R} if, by doing so, the regulator does not lose any contributors. Indeed, if the number of banks contributing towards a bail-in rescuing banks in \mathcal{B}' is larger than

³⁷One can show that $\min(\zeta^i, \eta^i(\mathcal{B})) = \min(\zeta^i, C^i(\mathcal{B}))$ for any bank i with a positive threat level $\eta^i(\mathcal{B}')$ when banks in \mathcal{R} are not rescued. The terms in the sums for each such bank are thus identical.

when rescuing banks in \mathcal{B} , i.e., $m(\mathcal{B}') \geq m(\mathcal{B})$, then this term is positive because $\mathcal{C}(\mathcal{B}')$ is the set of banks of size $m(\mathcal{B}')$ that maximizes contributions of size $\eta(\mathcal{B}')$.

Both Lemmas 5.2 and 5.5 imply that it is beneficial for banks to have only a small number of creditors. To be rescued in a bailout, the bank must cause large contagion effects. To be rescued in a bail-in, the bank's creditors need to be among the largest potential contributors to the rescue consortium. Both are more likely to happen when the losses caused by the bank's default are spread only across a few creditors. Because the regulator prefers sparsely connected networks, it follows that ex-ante incentives of banks are better aligned with the regulator's objective when he allows for partial intervention, rather than when restricting himself to complete rescues only.

Our final result relates the structure of the equilibrium partial bail-in with the structure of the optimal partial bailout.

Lemma 5.6. *Let $\mathcal{B} \subseteq \mathcal{B}'$ with $W_\lambda(s(\mathcal{B}')) \leq W_\lambda(s(\mathcal{B}))$. Then $W(\mathcal{B}') \leq W(\mathcal{B})$.*

For $\mathcal{B}' \in \mathcal{B}_P$, Lemma 5.6 shows that it cannot be optimal to rescue a subset of the banks that are bailed out in the threatened bailout: by Lemma 5.3, no bank would have any incentive to contribute to such a bail-in. Lemma 5.6, however, does not imply that all banks from the optimal bailout are rescued in the optimal bail-in, nor is that statement true in general. Condition 2 in Lemma 5.3 shows that, in order to incentive banks to participate, the regulator needs to propose bail-ins that rescue banks that are not bailed out. In the online appendix, we provide a numerical example, in which banks rescued in the optimal bailout are not rescued in the optimal bail-in.

6 Equilibrium Welfare Losses and Network Structure

In this section, we analyze the dependency of equilibrium welfare losses on the structure of the interbank network using data from the 2018 stress test of the European Banking Authority (EBA). We elaborate in Appendix D how we calibrate our model to the data set. To highlight more prominently the impact of the network structure on welfare, we shut down the price-mediated contagion channel for this calibration exercise. This corresponds to setting $\gamma = 0$ or, equivalently, assuming that all outside assets are held as cash. Detailed information on bilateral exposures is not publicly available. To compare the relative performance of different network structures, we fit a sparse and a dense network structure π_s and π_d , respectively, to the data from the EBA stress test. We then analyze the credibility of the regulator's threat and the equilibrium welfare losses as a function of the network structure $\pi_\mu := \mu\pi_s + (1-\mu)\pi_d$ for $\mu \in [0, 1]$.³⁸ We generate the dense network π_d following the maximum entropy method developed by Upper and Worms (2004). This method distributes interbank liabilities as evenly as possible among the counterparties, yielding a complete network. We generate the sparse network π_s using an iterated greedy algorithm, for which details are provided in

³⁸Craig and Von Peter (2014) show that the German interbank network has a core-periphery structure: while the 45 large core banks act as intermediaries and have many counterparties, the periphery banks trade only with core banks, but not with each other. The participating banks in the EBA stress test are 36 of the largest banks in Europe, which are all considered core banks. Therefore, we do not aim to estimate a core-periphery network to this data set but rather analyze the impact of a range of network structures of different sparsity on credibility and equilibrium welfare losses for the subnetwork of core banks.

Figure 5: The two plots show how welfare losses under different resolution plans and banks’ contributions to the equilibrium bail-in change as a function of the network $\pi_\mu = \mu\pi_s + (1-\mu)\pi_d$ as μ increases from 0 to 1. Thus, at the left edge of each plot, the network is equal to a dense network π_d and it gets progressively sparser as we move to the right until it is equal to a sparse network π_s at the right edge. Welfare losses and welfare impacts of banks’ contributions are shown relative to the welfare losses W_P in the complete bailout. Contributions of banks are shown cumulatively so that the contributed amount of a single bank corresponds to the distance between two consecutive lines.

Appendix D.³⁹ We then apply a shock to the assets of HSBC, Barclays, and Deutsche Bank with a shock size equal to their cash holdings, thereby wiping out the value of their non-interbank assets.

The left plot of Figure 5 shows the impact of the network structure on welfare losses under different resolution plans. As the network becomes sparser, liabilities among banks are more concentrated. This makes contagious defaults in absence of intervention more likely and the corresponding welfare losses W_N change discontinuously where this happens. For the chosen size of shocks, the threat is credible in all networks since W_N is smaller than welfare losses W_P in the complete bailout. This allows the coordination of a complete equilibrium bail-in as described in Theorem 3.10 with welfare losses equal to W_E . Contributions to the equilibrium bail-in are illustrated in the right plot of Figure 5, where it is evident that they increase as the network becomes sparser because free-riding incentives are reduced. The three main creditors of the shocked banks would suffer large losses without intervention and can, therefore, be incentivized to make large contributions. This leads to a continuous decrease in equilibrium welfare losses as the network gets sparser until we observe contagious defaults in the default cascade: because of the no-free-riding constraints, welfare losses in a bail-in can differ from W_N by at most the contribution of any participating bank. Therefore, discontinuous changes in W_N are reflected also in the equilibrium welfare losses. Nevertheless, equilibrium welfare losses in the sparsest network are 5.2% lower than in the most dense network despite the fact that without intervention, they would be 31.2% larger.

For the chosen shock sizes, there are no contagiously defaulting banks in the most dense network. This illustrates that even if the regulator’s threat is more credible in a dense network, equilibrium welfare losses are typically still decreasing in the sparsity of the network because of the reduced free-riding incentives. For larger shock sizes or a more lowly capitalized financial system, we would ob-

³⁹The resulting network π_d has 1260 edges, i.e., each of the 36 banks is connected to every other bank, and a normalized Gini index of 0.4556. The network π_s has 71 edges with a normalized Gini index of 0.9981. See Hurley and Rickard (2009) for a definition of the Gini index. The Gini index is a measure of sparsity, which we normalize to account for the fact that diagonal entries in any relative liability matrix are 0. The normalized Gini index is 0 for the symmetric complete network and 1 for a ring network.

serve that the credibility improves as the network becomes sparser: consistent with Lemma 3.4 and findings of earlier literature on systemic risk in absence of intervention (e.g., Allen and Gale (2000) and Acemoglu, Ozdaglar and Tahbaz-Salehi (2015)), dense connections amplify a large shock.

Finally, the left panel of Figure 5 illustrates the findings of Section 5, in which we consider interventions that may target only a subset of banks. For the chosen shock sizes, it turns out that in the optimal bailout, the regulator only rescues the contagiously defaulting banks and lets the fundamentally defaulting banks fail. This leads to welfare losses W_P^* , which coincides with W_N when there are no contagiously defaulting banks. In the partial equilibrium bail-in W_E^* , it is optimal to rescue every bank since contributions from the private sector can be solicited for the rescue of fundamentally defaulting banks. This is consistent with the predictions of Lemmas 5.2 and 5.5 below. Welfare losses W_E^* in the partial equilibrium bail-in with partial rescues are 38.5% lower than in the complete network structure. In this calibrated model, there are 7140 ways of applying idiosyncratic shocks to three banks in the network. Taking the average over all combinations of shocks, equilibrium welfare losses in the sparsest network are lower than in the most dense network by 13.96% for complete rescues and by 28.92% for partial rescues. These results suggest that structural policies aiming at sparsifying the financial network may significantly raise welfare.

7 Concluding Remarks

Various initiatives have been undertaken by central governments and monetary authorities, especially after the global financial crisis, to expand resolution plans and tools. Our paper makes a first step towards a systematic analysis of the incentives that govern alternative resolution plans. At the heart of our analysis is the credibility of the regulator’s no-intervention (or partial rescue) threat, given the desire of each bank to free-ride on the contributions of the government and of other banks. In a framework with complete rescues, the credibility determines whether a bail-in can be organized in equilibrium or whether the regulator is forced to a bailout. If the regulator is free to propose rescues that save only some banks but not others, threat levels vary across banks and determine the size of incentive-compatible contributions towards a bail-in.

We highlight the main forces impacting the credibility of the no-rescue threat. The threat fails to be credible for a given shock size if and only if the shock is heavily amplified through inefficient asset liquidation, bankruptcy costs, and negative feedback effects between densely connected banks in distress. The impact of the interbank network structure on the credibility is captured by a measure that we call the *total throughput* of defaulting banks, which reflects the rate at which losses spill over to solvent members of the economy, taking into account feedback effects between defaulting banks. Conditional on the banks’ levels of solvency, the total throughput depends entirely on the network structure, giving us a metric to rank the desirability of different network structures.

Our analysis has focused on the design of government interventions, given a particular financial structure. We have shown that when there is a credible bail-in proposal, it is preferable to a bailout because the size of the required public expenditures is lower. While our findings thus explain why public officials have called for substituting bail-ins for bailouts, they also explain why there have

been so few successful bail-ins: it may not be possible to construct a credible bail-in proposal. Moreover, our analysis shows that selective bail-ins and bailouts, where not all banks are rescued, may be preferable to inclusive policies. In our model, we can precisely define which banks should be rescued, thereby providing the regulator with a rational argument for this selectivity. The partial bailouts of the 2008 financial crisis were widely criticized for being determined more by influence and political connections than by such objective factors.

Our analysis reverses the presumptions concerning the relative desirability of sparse versus dense networks for intermediate shock sizes. This has obvious implications for the design of regulations that affect the network structure. These implications, as well as the broader implications of the interventions that we have described for ex-ante behavior, take us beyond the scope of this limited paper. For now, we simply note two such implications. First, because banks prefer a bailout over a bail-in, they benefit from additional market illiquidity. This implies that ex ante, banks have an incentive to invest into thinly-traded securities. Second, for a bank to be rescued in a partial bail-in, it is beneficial to borrow funds only from a few other banks so that contagion effects in case of the bank's default are highly concentrated. Then, free-riding incentives among creditors are smaller, making the rescue more appealing to the regulator.

This paves the way for future research on endogenous network formation. In such a model, banks anticipate which bail-in consortia are credible for which network structures, and hence choose their counterparties by taking into account their ex-ante expected contributions to an equilibrium bail-in plan. Such an endogenous network formation model adds an additional dimension to the moral hazard literature: through their interbank linkages, banks can control the likelihood of a public bailout as well as the likelihood to be included in the prevailing bail-in. Additionally, it would be desirable to account for the ex-ante risk taking decisions by banks as they maximize the value of their bailout option (as in Acharya and Yorulmazer (2007), Acharya, Shin and Yorulmazer (2011), and Farhi and Tirole (2012)).⁴⁰ By choosing the riskiness and the liquidity of their investments, banks can further influence the set of available resolution policies. Accounting for ex-ante risk taking behavior will lead to a comprehensive framework for the analysis of welfare maximizing rescue policies.

Figure 6: Consider an individually incentive-compatible bail-in (b, s) that induces asset price α , in which bank i contributes the largest incentive-compatible amount $\eta^i(\alpha, e)$. A rejection by bank i has an impact of $\lambda\eta^i(\alpha, 0) + g_\alpha(\eta^i(\alpha, e) - \eta^i(\alpha, 0))$ on welfare (top). If the regulator burns $\chi_C^i(\alpha) = (W_N - W_\lambda(b, s, (0, 1^{-i})))^+$ units of welfare in a proposal that is otherwise identical, he becomes indifferent between the residual bail-in without bank i and the default cascade (bottom). Thus, bank i can no longer free-ride on the contributions of the remaining banks.

A Welfare Burning

In this appendix, we define the minimal amount $\chi_C(\alpha)$ of welfare burning needed to eliminate free-riding incentives from an individually incentive-compatible bail-in with contributing banks in \mathcal{C} .

Lemma A.1. *Let $z(\alpha) := \alpha \ln(\alpha)$ and let z^{-1} be its inverse on the interval $[\frac{1}{e}, 1]$. Define the function $g_\alpha(x) := g(z^{-1}(z(\alpha) + \gamma x)) - g(\alpha)$, which is invertible for $\alpha \geq \alpha_{\text{ind}}$. For a set of banks \mathcal{C} , let $\chi_C^i(\alpha) := (W_N - W_P + g(\alpha_P) - g(\alpha) + \lambda \sum_{j \in \mathcal{C} \setminus \{i\}} \eta^j(\alpha, 0) - g_\alpha(\eta^i(\alpha, e) - \eta^i(\alpha, 0)))^+$ for any bank $i \in \mathcal{C}$. Moreover, let $\hat{\chi}_C(\alpha)$ denote the unique non-negative solution χ to*

$$-\frac{\alpha \ln(\alpha)}{\gamma} = \sum_{i \in \mathcal{C}} g_\alpha^{-1} \left(\left(W_N - W_P + g(\alpha_P) - \lambda \sum_{j \in \mathcal{C} \setminus \{i\}} \eta^j(\alpha, 0) - \chi \right)^+ \right) \quad (26)$$

if it exists and let $\hat{\chi}_C(\alpha) = 0$ otherwise. Define $\chi_C(\alpha) := \hat{\chi}_C(\alpha) \vee \max_{i \in \mathcal{C}} \chi_C^i(\alpha)$. Consider a bail-in (b, s) with accepting equilibrium $1 = (1, \dots, 1)$. Let $\mathcal{C} = \{i \mid b^i > 0\}$ and $\alpha = \bar{\alpha}(b, s, 1)$. Then

$$\lambda \sum_{i \notin \mathcal{C}} (s^i - s_0^i)^+ + \lambda \sum_{i \in \mathcal{C}} (\eta^i(\alpha, 0) - b^i)^+ \geq \chi_C(\alpha). \quad (27)$$

Figure 7: The construction of $\hat{\chi}_{\mathcal{C}}(\alpha)$ is illustrated for $\mathcal{C} = \{i_1, i_2, i_3\}$. It is the minimal amount of welfare burnt such that the welfare impact $\lambda\eta^i(\alpha, 0) + g_{\alpha}(x^i)$ caused by the rejection of any bank $i \in \mathcal{C}$ exceeds $W_N - W_{\lambda}(b, s, 1) - \hat{\chi}_{\mathcal{C}}(\alpha)$, subject to the constraint $\sum_{i \in \mathcal{C}} x^i \leq -\alpha \ln(\alpha)/\gamma$, which guarantees that the total amount liquidated does not depress the asset price below α . Note that $x^{i_3} = 0$ because the welfare impact of i_3 's rejection is large enough to deter free-riding without asset liquidation. If $\hat{\chi}_{\mathcal{C}}(\alpha) > 0$, then the constraint binds, that is, $x^{i_2} + x^{i_3} = -\alpha \ln(\alpha)/\gamma$. Otherwise, it would be possible to increase the welfare impact by banks i_1 and i_2 and decrease the amount of welfare burnt.

For the no-free-riding incentives to hold, the rejection by any bank must have an impact on welfare in excess of $W_N - W_{\lambda}(b, s, 1)$. It follows from (14) that the impact on welfare has two components: contributions up to $\eta(\alpha, 0)$ affect welfare directly by an amount $\lambda\eta(\alpha, 0)$, whereas contributions that exceed $\eta(\alpha, 0)$ by an amount x require asset liquidation and affect welfare through the trade-off $g_{\alpha}(x)$. A contribution of size $\eta^i(\alpha, 0) + x^i$ by bank i thus has a total impact on welfare of $\lambda\eta^i(\alpha, 0) + g_{\alpha}(x^i)$. Among individually incentive-compatible contributions, the welfare impact by bank i is maximized when i contributes $\eta^i(\alpha, e)$. If the maximal welfare impact is smaller than $W_N - W_{\lambda}(b, s, 1)$, the remaining value $\chi_{\mathcal{C}}^i(\alpha) = W_N - W_{\lambda}(b, s, 1) - \lambda\eta^i(\alpha, 0) - g_{\alpha}(\eta^i(\alpha, e) - \eta^i(\alpha, 0))$ has to be burnt; see Figure 6 for an illustration. Burning an amount equal to $\max_{i \in \mathcal{C}} \chi_{\mathcal{C}}^i(\alpha)$ thus deters free-riding by all banks when each bank liquidates the maximal incentive-compatible amount. However, asking each bank to contribute $\eta^i(\alpha, e)$ may require asset liquidation in excess of $-\ln(\alpha)/\gamma$, which would depress the asset price below α by (1). In that case, the regulator has to ask for lower contributions from banks that require aggregate liquidation of only $-\ln(\alpha)/\gamma$ and burn additional welfare to balance the reduced welfare impact of the contributing banks. The lowest amount of welfare burnt in that case is $\hat{\chi}_{\mathcal{C}}(\alpha)$; see Figure 7 for an illustration.

B Proofs of Results in Sections 2 and 3

B.1 Existence and Monotonicity of Clearing Equilibria

This appendix provides the proofs of Section 2, asserting existence and monotonicity of clearing equilibria, together with Pareto dominance of the greatest clearing equilibrium. We begin with the following auxiliary result, which provides us with an alternative expression for welfare losses.

Lemma B.1. *For any clearing equilibrium (p, ℓ, α) , the following identity holds*

$$W_{\lambda}(p, \alpha) = \sum_{i=1}^n (c^i + e^i - w^i - V^i(p, \alpha)) + \sum_{i \in \mathcal{D}(p, \ell, \alpha)} (1 + \lambda)\delta^i(p, \alpha). \quad (28)$$

Proof. Observe first that π is column-stochastic by construction, i.e., the columns sum up to 1. Thus, $\sum_i (\pi x)^i = \sum_i x^i$ for any vector x . Summing (4) for prices (p, α) , we obtain

$$\sum_{i=1}^n V^i(p, \alpha) = \sum_{i=1}^n (c^i + \alpha e^i - w^i) - \sum_{i \in \mathcal{D}(p, \ell, \alpha)} (c^i - w^i + \alpha e^i + (\pi p)^i - p^i).$$

It follows that

$$\sum_{i=1}^n (c^i + e^i - w^i - V^i(p, \alpha)) = \sum_{i=1}^n (1 - \alpha)e^i + \sum_{i \in \mathcal{D}(p, \ell, \alpha)} (c^i - w^i + \alpha e^i + (\pi p)^i - p^i). \quad (29)$$

The definition of a clearing payment vector in (3) implies that $p^i + w^i - \delta^i = \beta(c^i + \alpha e^i + (\pi p)^i)$ for any $i \in \mathcal{D}(p, \ell, \alpha)$. Therefore, we obtain

$$c^i + \alpha e^i + (\pi p)^i - (p^i + w^i - \delta^i) = (1 - \beta)(c^i + \alpha e^i + (\pi p)^i) \quad (30)$$

for any $i \in \mathcal{D}(p, \ell, \alpha)$. Equation (28) now follows from (29) and (30). \square

Since the equity value of any bank is monotonically increasing in prices, a direct consequence of Lemma B.1 is the fact that welfare losses are monotonically decreasing in prices. For the sake of reference, we state this property as a lemma.

Lemma B.2. *Any bank i 's value of equity $V^i(p, \alpha)$ is non-decreasing and welfare losses $W_\lambda(p, \alpha)$ are non-increasing in α and p^j for any j .*

Proof. Bank i 's value in (4) is equal to $V^i(p, \alpha) = (\pi p + c + \alpha e - w - L)^i 1_{\{p^i = L^i\}}$, which is non-decreasing in (p, α) . This also implies that the first term of welfare losses in (28) is non-increasing in (p, α) . The second term in (28) is non-increasing in (p, α) by definition of $\delta(p, \alpha)$ in (5). \square

Proof of Lemma 2.2. Let $\mathcal{L} := [0, e^1] \times \cdots \times [0, e^n]$ denote the set of possible liquidation decisions by the banks. Fix a vector p of interbank repayments and define the operator $\Phi_p : \mathcal{L} \rightarrow \mathcal{L}$ by setting $\Phi_p^i(x) := \ell^i(\alpha(x), p)$ for $i = 1, \dots, n$, where $\alpha(x)$ and $\ell(\alpha, p)$ are defined in (1) and (2). By construction, a pair (α, ℓ) is a solution to (1) and (2) if and only if it is of the form $(\alpha(x), x)$ for a fixed point x of Φ_p . Since both α and ℓ^i are non-increasing, Φ_p^i is non-decreasing. Therefore, Tarski's fixed-point theorem implies that the set of Φ_p 's fixed points forms a complete lattice. In particular, there exists a fixed point \underline{x} such that $\underline{x}^i \leq x^i$ for each i and any other fixed point x of Φ_p . Let $\ell_p = \underline{x}$ and $\alpha_p = \alpha(\ell_p)$. By construction, (α_p, ℓ_p) satisfies (1) and (2) and for any other solution $(\tilde{\alpha}, \tilde{\ell})$, we have $\tilde{\alpha} = \exp(-\gamma \sum_{i=1}^n \tilde{\ell}^i) \leq \exp(-\gamma \sum_{i=1}^n \ell_p^i) = \alpha_p$. \square

Before proving existence of clearing equilibria, we show the following comparison result for fixed points that will be used many times throughout our analysis.

Lemma B.3. *Let f and g be two non-decreasing functions mapping a compact set \mathcal{X} into itself. Let \bar{x}_f (\underline{x}_f) and \bar{x}_g (\underline{x}_g) denote the largest (smallest) fixed points of f and g , respectively, that exist by Tarski's fixed point theorem. If $f(\bar{x}_g) \geq g(\bar{x}_g)$, then $\bar{x}_f \geq \bar{x}_g$. If $f(\underline{x}_g) \leq g(\underline{x}_g)$, then $\underline{x}_f \geq \underline{x}_g$.*

Proof. Let $\bar{x}_n := f^{(n)}(\bar{x}_g)$ define the n -fold application of f to \bar{x}_g . Since $f(\bar{x}_g) \geq g(\bar{x}_g) = \bar{x}_g$ and f is non-decreasing, it follows that $(\bar{x}_n)_{n \geq 1}$ is non-decreasing in each component. Because of compactness, $(\bar{x}_n)_{n \geq 1}$ converges to some fixed point \bar{x}_∞ of f . Therefore, $\bar{x}_g \leq \bar{x}_\infty \leq \bar{x}_f$ because \bar{x}_f is the largest fixed point of f . The analogous argument shows $\underline{x}_g \geq \lim_{n \rightarrow \infty} f^{(n)}(\underline{x}_g) \geq \underline{x}_f$. \square

We are now ready to prove Lemma 2.1.

Proof of Lemma 2.1. Let $\mathcal{P} := [0, L^1] \times \cdots \times [0, L^n]$ denote the set of possible clearing payment vectors. For fixed p , let (α_p, ℓ_p) be the solutions to (1) and (2) of Lemma 2.2. Define the operator $\Phi : \mathcal{P} \rightarrow \mathcal{P}$ by setting

$$\Phi^i(p) := \begin{cases} L^i & \text{if } c^i + \alpha_p e^i + (\pi p)^i \geq L^i + w^i, \\ \left(\beta(c + \alpha_p e + \pi p)^i - w^i \right)^+ & \text{otherwise.} \end{cases} \quad (31)$$

The definition of ℓ_p in (2) implies that $c^i + \alpha_p e^i + (\pi p)^i \geq L^i + w^i$ if and only if $c^i + \alpha_p \ell_p^i + (\pi p)^i \geq L^i + w^i$. Therefore, the definition of a clearing equilibrium implies that a clearing payment vector p is a fixed point of Φ . We proceed to show that Φ is monotone. It follows directly from Eq. (2) that, for any i , $\ell^i(\alpha, p)$ is non-increasing in p^j for any j . Using the definition of Φ_p given in the proof of Lemma 2.2, we deduce that $\Phi_{(\tilde{p}^j, p^{-j})}^i(\ell_p) \leq \Phi_p^i(\ell_p)$ for any $\tilde{p}^j > p^j$. Therefore, Lemma B.3 shows that $\ell_{(\tilde{p}^j, p^{-j})}^i \leq \ell_p^i$ and hence $\alpha_{(\tilde{p}^j, p^{-j})} \geq \alpha_p$. This shows that $p \mapsto \alpha_p$ is non-decreasing, hence so is Φ^i . Tarski's fixed point thus implies the existence of fixed points $\underline{p} \leq \bar{p}$ with $\underline{p} \leq p \leq \bar{p}$ for any fixed point p . The first statement now follows from the monotonicity of the maps $p \mapsto \alpha_p$ and $p \mapsto \ell_p$ by setting $\underline{\alpha} = \alpha_{\underline{p}}$, $\bar{\alpha} = \alpha_{\bar{p}}$, $\underline{\ell} = \ell_{\underline{p}}$, and $\bar{\ell} = \ell_{\bar{p}}$. Monotonicity of the banks' equity value and welfare losses now follows from Lemma B.2 \square

B.2 Bailouts

This appendix shows that welfare-maximizing bailouts are of the form given in Lemma 3.2. We begin this appendix with the following auxiliary lemma.

Lemma B.4. *The function $g(\alpha) = \alpha \left(\frac{\lambda}{\gamma} \ln(\alpha) - \sum_{i=1}^n e^i \right)$ is strictly convex, attaining its global minimum at α_{ind} defined in (10).*

Proof. Since g is differentiable on $(0, \infty)$, the product rule yields

$$g'(\alpha) = \frac{\lambda}{\gamma} (1 + \ln(\alpha)) - \sum_{i=1}^n e^i, \quad g''(\alpha) = \frac{\lambda}{\gamma \alpha} > 0,$$

proving that g is strictly convex. Since $g'(\alpha_{\text{ind}}) = 0$, α_{ind} is the global minimizer of g . \square

Proof of Lemma 3.1. Let s denote a vector of subsidies of a complete bailout with $s^i \leq s_0^i$ for every bank i . Since every bank is rescued when subsidies s are awarded, the definition of s_0 implies that $\ell^i = \frac{1}{\bar{\alpha}(s)} (s_0^i - s^i)$ for any bank i . It follows from (1) that

$$\bar{\alpha}(s) = \exp \left(- \frac{\gamma}{\bar{\alpha}(s)} \sum_{i=1}^n (s_0^i - s^i) \right). \quad (32)$$

Solving (32) for $\sum_{i=1}^n s^i$ and substituting into (7) shows (9). \square

Proof of Lemma 3.2. Let s denote a vector of subsidies that maximize welfare in a complete bailout. Because a minimal subsidy of s_L is needed to support the clearing payment vector L , it follows that $s^i \geq s_L^i$ for every bank i . Since any subsidies beyond s_0 have infinitesimal welfare impact $-\lambda$, it follows that $s^i \leq s_0^i$ for every bank i . Therefore, $\ell^i = \frac{1}{\alpha_P}(s_0^i - s^i)$ for any bank i , which implies

$$\alpha_P = \exp\left(-\frac{\gamma}{\alpha_P} \sum_{i=1}^n (s_0^i - s^i)\right). \quad (33)$$

Lemma 3.1 establishes that welfare in the complete bailout depends on the awarded subsidies only through $g(\alpha_P)$. Since g is differentiable, it follows from B.4 that α_P is either a boundary point or it is equal to α_{ind} . Since (33) is monotonic in the awarded subsidies, boundary points are attained at α_L and 1 when the subsidies are equal to s_L and s_0 , respectively. It follows from monotonicity in (33) that $\alpha_P = \max(\min(\alpha_{\text{ind}}, 1), \alpha_L)$. Inverting (33) for $\sum_{i=1}^n s^i$ yields (11). \square

B.3 Incentives and Bail-In Selection

In this appendix we provide the proofs of the results in Section 3.4, characterizing accepting equilibria and how the regulator can select among multiple accepting equilibria. We begin with the following auxiliary result, formalizing that a bank is better off rejecting a bail-in proposal if its participation is not needed for the regulator to proceed with the bail-in. It will be convenient to denote by $V^i(b, s, a) = V^i(\bar{p}(b, s, a), \bar{\alpha}(b, s, a))$ bank i 's value of equity in the bail-in (b, s, a) . Similarly, let $V^i(s) = V^i(\bar{p}(s), \bar{\alpha}(s))$ denote bank i 's value of equity in the bailout with subsidies s .

Lemma B.5. *Fix a feasible bail-in proposal (b, s) with $b^i > 0$ for some bank i . For any response a^{-i} by i 's competitors, we have $V^j(b, s, (0, a^{-i})) \geq V^j(b, s, (1, a^{-i}))$ for any bank j . Moreover, the inequality is strict if $j = i$.*

Proof. The two financial systems resulting from $(b, s, (0, a^{-i}))$ and $(b, s, (1, a^{-i}))$ are identical up to the financial commitments by bank i , which are larger by b^i in the latter system. The result thus follows from Statement 3 in Lemma F.3 of the online appendix and monotonicity in Lemma B.2. \square

Proof of Lemma 3.5. Fix a feasible proposal (b, s) with accepting equilibrium response a . We first show necessity of the stated conditions. To this end, fix a bank i with $b^i > 0$ and suppose towards a contradiction that $a^i = 1$ but at least one of the two conditions is violated. Consider first the case where Condition 1 is violated. Then the regulator proceeds with a bail-in even if bank i rejects the proposal. Therefore, the resulting subsidies are the same under a and $(0, a^{-i})$. It follows from Lemma B.5 that bank i is strictly better off under $(0, a^{-i})$, contradicting the assumption that a is an equilibrium. Consider now the case where Condition 2 is violated. Because (b, s) is feasible, bank i can afford to pay its liabilities $L^i + w^i$ and the bail-in contribution b^i . Together with the negation of Condition 2, we obtain

$$L^i + w^i \leq c^i + s^i - b^i + \alpha(b, s, (1, a^{-i}))e^i + \sum_{j=1}^n \pi^{ij} L^j < c^i + \alpha_N e^i + \sum_{j=1}^n \pi^{ij} p_N^j \quad (34)$$

This shows that bank i is solvent in the default cascade. Therefore, subtracting $L^i + w^i$ in (34) implies that $V_N^i > V^i(b, s, (1, a^{-i}))$, which is again a contradiction.

For sufficiency, Condition 1 implies that the regulator will react to a rejection by any bank by letting a default cascade occur. By Condition 2, such an outcome makes bank i worse off. It is thus optimal for bank i to accept the proposal. \square

Proof of Lemma 3.6. Fix a bail-in (b, s) with an accepting equilibrium a_k . Let $\mathcal{B} = \{i \mid b^i 1_{\{a_k^i=1\}}\}$ denote the set of banks making a positive contribution in (b, s, a_k) . Define a bail-in (\tilde{b}, \tilde{s}) by setting $\tilde{b}^i = b^i 1_{\{i \in \mathcal{B}\}}$ and $\tilde{s}^i = s^i$ for $i = 1, \dots, n$. We proceed to show that $1 = (1, \dots, 1)$ is an accepting equilibrium response to (\tilde{b}, \tilde{s}) . Note that, by convention, the only available response for any bank $i \in \mathcal{B}^c$ is to accept the proposal; see Footnote 15. For $i \in \mathcal{B}$, note that Lemma 3.5 shows that the stated Conditions 1 and 2 are satisfied in (b, s, a_k) for any $i \in \mathcal{B}$ since a_k is an accepting equilibrium. Because each bank makes the same contribution in $(\tilde{b}, \tilde{s}, 1)$ as in (b, s, a_k) , it follows that $\bar{\alpha}(\tilde{b}, \tilde{s}, 1) = \alpha(b, s, a_k)$, $W_\lambda(b, s, 1) = W_\lambda(b, s, a_k)$, as well as $W_\lambda(b, s, (0, 1^{-i})) = W_\lambda(b, s, (0, a_k^{-i}))$ for every $i \in \mathcal{B}$. Therefore, Conditions 1 and 2 of Lemma 3.5 are satisfied also in (\tilde{b}, \tilde{s}) for any $i \in \mathcal{B}$. Lemma 3.5 thus implies that 1 is an accepting equilibrium response to (\tilde{b}, \tilde{s}) . To show uniqueness, observe that the regulator will not proceed with the bail-in if only a proper subset of \mathcal{B} accepts the proposal due to Condition 1 of Lemma 3.5. \square

Proof of Lemma 3.7. Fix a complete bail-in proposal (b, s) with accepting equilibrium a . It follows from Lemma 3.5 that the value of any bank in $\mathcal{A}(b) = \{i \mid b^i > 0\}$ is at least as high in (b, s, a) as in a rejecting equilibrium as otherwise bank i would have not accepted the proposal. By definition of an accepting equilibrium, welfare losses are at most as high as in a rejecting equilibrium, because otherwise the regulator would not have proceeded with the bail-in. This shows that (a) no rejecting equilibrium can subgame Pareto dominate a and (b) a rejecting equilibrium is subgame Pareto efficient only if it is equivalent to (b, s, a) . Since there are only two possible outcomes in a rejecting equilibrium (public bailout and no rescue), the complete bail-in proposal (b, s) has to coincide with the complete bailout as, by definition, it rescues every bank in the system.

Let $\tilde{\mathcal{A}}$ denote the set of accepting equilibria that minimize welfare losses. It remains to show that at least one of them is subgame Pareto efficient. Let $a \in \mathcal{A}$ denote the accepting equilibrium leading to the highest asset price among accepting equilibria in \mathcal{A} . Suppose towards a contradiction that there exists a continuation equilibrium \tilde{a} that Pareto dominates a . This necessitates $W_\lambda(b, s, \tilde{a}) \leq W_\lambda(b, s, a)$, which implies that \tilde{a} is an accepting equilibrium in \mathcal{A} . Let \mathcal{C} and $\tilde{\mathcal{C}}$ denote the set of banks which accept the proposal in a and \tilde{a} , respectively. By Condition 1 of Lemma 3.5, the regulator rejects the bail-in if only a strict subset of \mathcal{C} accepts the proposal. Since \tilde{a} is an accepting equilibrium, $\tilde{\mathcal{C}}$ is not a subset of \mathcal{C} and hence $\tilde{\mathcal{C}} \setminus \mathcal{C} \neq \emptyset$. By maximality of a in \mathcal{A} , we have $\alpha(b, s, \tilde{a}) \leq \alpha(b, s, a)$. Thus, because each bank in $\tilde{\mathcal{C}} \setminus \mathcal{C}$ makes a positive contribution in \tilde{a} but not in a , each such bank is strictly worse off in \tilde{a} than in a . This contradicts the assumption that \tilde{a} Pareto dominates a , which concludes the proof. \square

B.4 Credibility and Existence of Subgame Pareto Efficient Equilibria

In this appendix we prove Lemma 2.3, which establishes existence of subgame Pareto-efficient continuation equilibria after the proposal of any bail-in. In order to present the proofs as succinctly as possible, we invoke Proposition 3.3 to deal with the case when the threat fails to be credible. The proof of Proposition 3.3 does not rely on Lemma 2.3: existence of equilibria when the threat fails to be credible follows directly from the existence of strictly dominant strategies.

Proof of Proposition 3.3. Fix a feasible proposal (b, s) and any response vector a . Because the threat fails to be credible, the regulator will never respond with “no intervention”. Since any bank i with $b^i - s^i > 0$ is strictly worse off in (b, s) than in a complete rescue without its participation (e.g., bailout or bail-in by residual consortium) by Lemma B.5, rejection is the strictly dominant action for any such bank. This shows that the regulator cannot get any contributions from banks, hence the optimal bailout of Lemma 3.2 is the only possible equilibrium outcome. \square

Together with the characterization of accepting equilibria in Lemma 3.5, Proposition 3.3 allows us to prove Lemma 2.3.

Proof of Lemma 2.3. If the threat fails to be credible, Proposition 3.3 establishes that a rejecting equilibrium exists after any proposal (b, s) . Suppose, therefore, that the threat is credible. Fix a feasible proposal (b, s) and let 0 denote the vector of unanimous rejections by the banks. The credibility of the threat imposes that $W_N \leq W_P \leq W_\lambda(b, s, 0)$, where we have used the fact that without participation of the banks, the optimal rescue is the public bailout of Lemma 3.2. The regulator thus chooses $r(b, s, 0) = \text{“no intervention”}$. If no bank in $\mathcal{A}(b)$ has a profitable unilateral deviation to the vector of unanimous rejections, then that response is a rejecting equilibrium. Suppose, therefore, that there exists a bank $i \in \mathcal{A}(b)$ with a profitable unilateral deviation and let a_i denote the corresponding action profile. We will show that a_i is an equilibrium response.

For a_i to be a profitable deviation for bank i , two conditions must hold. First, it is necessary that $r(b, s, a_i) = \text{“bail-in”}$ as otherwise, bank i ’s value of equity would be equal to V_N^i both when i accepts and when i rejects the proposal. Second, we must have that $V^i(b, s, a_i) > V_N^i$. This condition is equivalent to $b^i - s^i < \sum_{j=1}^n \pi^{ij}(L^j - p_N^j) + (\alpha(b, s, a_i) - \alpha_N)e^i$, i.e., Condition 2 of Lemma 3.5 is satisfied for bank i . Since, by construction, $(0, a_i^{-i})$ is the vector of unanimous rejections, it follows that $W_\lambda(b, s, (0, a_i^{-i})) = W_\lambda(b, s, 0) \geq W_N$, i.e., Condition 1 of Lemma 3.5 is satisfied for bank i as well.

It remains to show that for any bank $j \neq i$, either the conditions of Lemma 3.5 is violated. For the regulator to choose “bail-in” in reaction to a_i , it is necessary that $W_\lambda(b, s, a_i) < W_N$. Since $(0, a_i^{-j}) = a_i$ for any bank $j \neq i$, it follows that $W_\lambda(b, s, (0, a_i^{-j})) = W_\lambda(b, s, a_i) < W_N$ for any such bank. Therefore, Condition 1 of Lemma 3.5 is violated for any bank in $\mathcal{A}(b) \setminus \{i\}$. An application of Lemma 3.5 thus shows that a_i is an accepting equilibrium. \square

We conclude this appendix by proving that the regulator’s threat is credible if and only if the amplification of the shock through the network is below the threshold given in Lemma 3.4.

Proof of Lemma 3.4. Observe first that $(L^i + w^i - c^i - e^i - (\pi L)^i)^- = (s_0^i - e^i)^+ = s_0^i - e^i - (e^i - s_0^i)^+$. It follows from (28) and the definitions of S_0 and S_N that welfare in the default cascade can be written as

$$W_N = S_N - S_0 + \sum_{i=1}^n (e^i + (e^i - s_0^i)^+) + (1 + \lambda) \sum_{i \in \mathcal{D}(p_N, \ell_N, \alpha_N)} \delta^i(p_N, \alpha_N).$$

Lemma 3.2 shows that $W_P = \sum_{i=1}^n e^i + \lambda S_0 + g(\alpha_P) + \lambda \sum_{i \in \mathcal{D}(p_N, \ell_N, \alpha_N)} \delta^i(p_N, \alpha_N)$. Solving the inequality $W_N - W_P \leq 0$ for $S_N - S_0$ using the above expressions for W_N and W_P , we obtain (12). \square

C Proof of Theorem 3.10

We begin this section by showing that without loss of generality, we can restrict our attention to bail-ins, where each bank either makes a contribution or receives a subsidy. Moreover, because the regulator can anticipate the banks' responses, we may also restrict our attention to bail-ins that allow response vector 1 in equilibrium.

Lemma C.1. *For any proposed bail-in (b, s) with accepting equilibrium response a , there exists a proposal (\tilde{b}, \tilde{s}) with accepting continuation equilibrium \tilde{a} such that $\tilde{b}^i \tilde{s}^i = 0$ and $\tilde{a}^i = 1$ for every bank i , and $W_\lambda(\tilde{b}, \tilde{s}, \tilde{a}) = W_\lambda(b, s, a)$.*

Proof. Fix a bail-in proposal (b, s) with accepting equilibrium response a . The existence of an accepting equilibrium a implies via Lemma 3.7 that either (b, s) is the public bailout of Lemma 3.2 or that the threat is credible. In the former case, the statement holds trivially, hence suppose that the threat is credible. Denote by $\mathcal{C} = \{b^i - s^i > 0, a^i = 1\}$ the set of banks which make a positive net contribution. Define the proposal (\tilde{b}, \tilde{s}) by setting $\tilde{b}^i = (b^i 1_{\{a^i=1\}} - s^i)^+$ and $\tilde{s}^i = (s^i - b^i 1_{\{a^i=1\}})^+$, and let $\tilde{a} = (1, \dots, 1)$ be the response vector of unanimous acceptance. It follows straight from the construction of (\tilde{b}, \tilde{s}) that $\tilde{b}^i 1_{\{\tilde{a}^i=1\}} - \tilde{s}^i = b^i 1_{\{a^i=1\}} - s^i$ for any bank i and hence each bank's net contribution remains unchanged. This implies that clearing equilibria coincide both in $(\tilde{b}, \tilde{s}, \tilde{a})$ and (b, s, a) and also in $(\tilde{b}, \tilde{s}, (0, \tilde{a}^{-i}))$ and $(b, s, (0, a^{-i}))$ for any $i \in \mathcal{C}$. It follows that

$$\begin{aligned} W_\lambda(\tilde{b}, \tilde{s}, \tilde{a}) &= W(\bar{p}(\tilde{b}, \tilde{s}, \tilde{a}), \bar{\alpha}(\tilde{b}, \tilde{s}, \tilde{a})) + \lambda \sum_{i=1}^n (\tilde{s}^i - \tilde{b}^i 1_{\{\tilde{a}^i=1\}}) \\ &= W(\bar{p}(b, s, a), \bar{\alpha}(b, s, a)) + \lambda \sum_{i=1}^n (s^i - b^i 1_{\{a^i=1\}}) = W_\lambda(b, s, a) \end{aligned}$$

and, in a similar fashion, that $W_\lambda(\tilde{b}, \tilde{s}, (0, \tilde{a}^{-i})) = W_\lambda(b, s, (0, a^{-i}))$ for any $i \in \mathcal{C}$. To conclude that \tilde{a} is an accepting equilibrium, it remains to verify Condition 2 of Lemma 3.5. Since a is an accepting equilibrium for (b, s) , Lemma 3.5 implies that

$$\tilde{b}^i - \tilde{s}^i = b^i - s^i \leq \sum_{j=1}^n \pi^{ij} (\bar{p}^j(b, s, a) - p_N^j) + (\bar{\alpha}(b, s, a) - \alpha_N) e^i$$

for every $i \in \mathcal{C}$. Because the clearing equilibria under $(\tilde{b}, \tilde{s}, \tilde{a})$ and (b, s, a) coincide, this shows that Condition 2 of Lemma 3.5 is satisfied in $(\tilde{b}, \tilde{s}, \tilde{a})$. An application of Lemma 3.5 thus shows that \tilde{a} is an accepting equilibrium response to (\tilde{b}, \tilde{s}) . \square

Because every bank is rescued in a complete feasible bail-in, the shortfall of each bank i before liquidation is at most e^i . The liquidated amount by any bank i is thus inversely proportional to the asset price. This imposes a lower bound on the asset price of $\frac{1}{e} = \exp(-1)$.

Lemma C.2. *Let (b, s) be a complete feasible bail-in proposal. In any response a , each bank i liquidates $\ell^i(b, s, a) = \frac{1}{\alpha}(L^i + w^i + b^i 1_{\{a^i=1\}} - c^i - s^i - (\pi L)^i)^+$ and $\alpha(b, s, a) \geq \frac{1}{e}$.*

Proof. Since (b, s) is a complete rescue, Lemma 2.2 implies that $(\alpha(b, s, a), \ell(b, s, a))$ is the solution to (1) and (2) for $p = L$ with the largest asset price. By feasibility,

$$L^i + w^i + b^i 1_{\{a^i=1\}} - c^i - s^i - (\pi L)^i \leq \alpha(b, s, a)e^i \leq \alpha(b, s, a)e^i.$$

This shows that $\ell^i(b, s, a)$ is indeed of the desired form. Therefore, $\alpha(b, s, a)$ is a fixed point of the function $f_{x,y}$ in Lemma F.2 for $y = 0$ and $x = \gamma \sum_{i=1}^n (L^i + w^i + b^i 1_{\{a^i=1\}} - c^i - s^i - (\pi L)^i)^+$. Since $\alpha(b, s, a)$ is the largest fixed point of f on $(0, 1]$, Lemma F.2 implies that $\alpha(b, s, a) \geq \frac{1}{e}$. \square

Due to Lemma C.1, we may restrict attention to bail-in proposals (b, s) , in which $b^i s^i = 0$ for every bank i . Then, liquidation and welfare losses take a simple form as stated in Lemma 3.8.

Proof of Lemma 3.8. Fix a bail-in (b, s) with an accepting equilibrium a such that $b^i s^i = 0$ for every bank i . Let $\alpha = \alpha(b, s, a)$ for the sake of brevity. Lemma C.2 shows that each bank i liquidates an amount $\ell^i(b, s, a) = \frac{1}{\alpha}(s_0^i - b_0^i + b^i 1_{\{a^i=1\}} - s^i)^+$. We begin by showing that this coincides with

$$\ell^i(b, s, a) = \frac{1}{\alpha}(s_0^i - \min(s^i, s_0^i) + (b^i - \min(b^i, b_0^i))1_{\{a^i=1\}}). \quad (35)$$

Consider first a bank i with $s_0^i > 0$. This implies that $b_0^i = 0$ by definition. If $s^i > 0$, then $b^i = 0$ by assumption and hence $\ell^i(b, s, a) = \frac{1}{\alpha}(s_0^i - s^i)^+ = \frac{1}{\alpha}(s^i - \min(s^i, s_0^i))$. This coincides with (35). If $s^i = 0$ instead, then $\ell^i(b, s, a) = \frac{1}{\alpha}(s_0^i + b^i 1_{\{a^i=1\}})$ also coincides with (35). Next, consider a bank i with $b_0^i > 0$. For such a bank, $s_0^i = 0$ by definition. If $s^i > 0$, then $b^i = 0$ by assumption and hence $\ell^i(b, s, a) = 0$, which coincides with (35). If $s^i = 0$, then

$$\ell^i(b, s, a) = (b^i 1_{\{a^i=1\}} - b_0^i)^+ = (b^i - b_0^i)^+ 1_{\{a^i=1\}} = (b^i - \min(b^i, b_0^i))1_{\{a^i=1\}},$$

showing that (35) also holds in this case. It follows from (1), (35), and the elementary identity $\min(s^i, s_0^i) = s^i - (s^i - s_0^i)^+$ that

$$\sum_{i=1}^n (s^i - b^i 1_{\{a^i=1\}}) = \sum_{i=1}^n (s_0^i + (s^i - s_0^i)^+ - \min(b^i, b_0^i)1_{\{a^i=1\}}) + \frac{\alpha \ln(\alpha)}{\gamma}.$$

The result now follows from (7), Lemma 3.2, and the specific form of g . \square

Lemma 3.9 states that among all individually incentive-compatible bail-ins with contributing banks in \mathcal{C} that induce asset price α , welfare is maximized for bail-ins with contributions $\eta^i(\alpha, \ell)$ by banks $i \in \mathcal{C}$ for any vector ℓ of asset liquidation that induces asset price α .

Proof of Lemma 3.9. Fix a complete feasible bail-in proposal (b, s) with accepting equilibrium a . By Lemma C.1 we may assume without loss of generality that $b^i s^i = 0$ and $a^i = 1$ for each bank i . For the sake of brevity, denote $\alpha = \alpha(b, s, 1)$. Since (b, s) is a complete rescue, it follows that $s \geq s(\alpha, e)$. Condition 2 of Lemma 3.5 and feasibility imply that $b^i \leq \eta^i(\alpha, e)$ for each $i \in \mathcal{C}$.

Define the bail-in proposal (\tilde{b}, \tilde{s}) by setting $\tilde{b}^i = \max(b^i, \eta^i(\alpha, 0))$ for each bank $i \in \mathcal{C}$ and $\tilde{s}^i = \min(s^i, s_0^i)$ for each bank $i \notin \mathcal{C}$. Because subsidies beyond s_0 and contributions below $\eta^i(\alpha, 0)$ do not prevent or require any liquidation, it follows that $\alpha(\tilde{b}, \tilde{s}, 1) = \alpha$. Therefore, Lemma 3.8 implies that subsidies beyond s_0 and contributions below $\eta^i(\alpha, 0)$ are welfare decreasing, i.e., $W_\lambda(b, s, 1) \geq W_\lambda(\tilde{b}, \tilde{s}, 1)$. Applying Lemma 3.8 for the proposal (\tilde{b}, \tilde{s}) thus yields

$$W_\lambda(b, s, 1) \geq W_\lambda(\tilde{b}, \tilde{s}, 1) = W_P - g(\alpha_P) + g(\alpha) - \lambda \sum_{i \in \mathcal{C}} \eta^i(\alpha, 0), \quad (36)$$

where we have used that $\min(\tilde{b}^i, b_0^i) = \eta^i(\alpha, 0)$. This shows the first statement. The final statement follows by observing that the inequality in (36) holds with equality precisely if $\eta^i(\alpha, 0) \leq b^i$ for each bank $i \in \mathcal{C}$ and $s^i \leq s_0^i$ for each bank $i \notin \mathcal{C}$. \square

Next, we show that $\chi_{\mathcal{C}}(\alpha)$ in Lemma A.1 is well-defined. Moreover, any incentive-compatible bail-in with contributing banks in \mathcal{C} that induces asset price α burns at least $\chi_{\mathcal{C}}(\alpha)$ units of welfare.

Proof of Lemma A.1. Fix $\alpha \geq \alpha_{\text{ind}}$. We start by showing that (26) has a unique non-negative solution if one exists. Lemma B.4 shows that g is increasing and hence invertible on the interval $[\alpha_{\text{ind}}, 1]$. Let g^{-1} denote the inverse on $[\alpha_{\text{ind}}, 1]$ and define the function $\hat{\alpha}(x) := g^{-1}(x + g(\alpha))$ for $x \geq 0$. It is easy to check that $\hat{\alpha}(x) \geq \alpha$ and $g_\alpha^{-1}(x) = \frac{1}{\gamma}(z(\hat{\alpha}(x)) - z(\alpha))$ for any $x \geq 0$. It follows from the formula for the inverse of the derivative that

$$\hat{\alpha}'(x) = \frac{1}{g'(g^{-1}(x + g(\alpha)))} = \frac{1}{g'(\hat{\alpha}_x(\alpha))} > 0,$$

where we have used that $\hat{\alpha}(x) \geq \alpha \geq \alpha_{\text{ind}}$. Since $\hat{\alpha}(x) \geq \alpha_{\text{ind}} \geq \frac{1}{e}$ and z is increasing on $[\frac{1}{e}, 1]$, it follows from the chain rule that $(g_\alpha^{-1})'(x) = \frac{1}{\gamma} z'(\hat{\alpha}(x)) \hat{\alpha}'(x) > 0$. Since g_α^{-1} is strictly increasing, the right-hand side of (26) is strictly decreasing in χ . Thus, if the right-hand side is lower than the left-hand side for $\chi = 0$, there exists no non-negative solution. If the right-hand side is greater than or equal to the left-hand side for $\chi = 0$, there exists precisely one non-negative solution. The fact that $\chi_{\mathcal{C}}(\alpha)$ is a lower bound for welfare burning in an accepting equilibrium (b, s) with contributing banks \mathcal{C} and $\alpha = \bar{\alpha}(b, s, 1)$ now follows from Lemma C.3. \square

Lemmas 3.8 and 3.9 together imply that any bail-in satisfying Conditions (i)–(iv) in Defini-

tion 3.2, if accepted, induces welfare losses

$$W_{\mathcal{C}}(\alpha) := W_P - g(\alpha_P) + g(\alpha) - \lambda \sum_{i \in \mathcal{C}} \eta^i(\alpha, 0) + \chi_{\mathcal{C}}(\alpha).$$

The following lemma establishes that this is a lower bound for welfare losses that can be attained by a bail-in with contributing banks \mathcal{C} that induces asset price α .

Lemma C.3. *Let (b, s) be a complete feasible bail-in proposal with accepting equilibrium a . Let $\mathcal{C} := \{i \mid b^i 1_{\{a^i=1\}} > 0\}$ and denote $\alpha = \bar{\alpha}(b, s, a)$ for the sake of brevity. Then $W_{\lambda}(b, s, a) \geq W_{\mathcal{C}}(\alpha)$ and the inequality binds if and only if $(b, s) \in \Xi(\mathcal{C}, \alpha)$.*

Proof. Let (b, s) be a complete feasible bail-in proposal with accepting equilibrium a . By Lemma C.1, we may assume without loss of generality that $b^i s^i = 0$ and $a^i = 1$ for every bank i . It follows in the same way as in the proof of Lemma 3.9 that $b^i \leq \eta^i(\alpha, e)$ for each $i \in \mathcal{C}$ and $s^i \geq s^i(\alpha, e)$ for each $i \notin \mathcal{C}$. Therefore, Conditions 1 and 2 of Definition 3.2 are satisfied.

Define the bail-in proposal (\tilde{b}, \tilde{s}) by setting $\tilde{b}^i = \max(b^i, \eta^i(\alpha, 0))$ for each bank $i \in \mathcal{C}$ and $\tilde{s}^i = \min(s^i, s_0^i)$ for each bank $i \notin \mathcal{C}$. It follows as in the proof of Lemma 3.9 that $\alpha(\tilde{b}, \tilde{s}, 1) = \alpha$ and

$$W_{\lambda}(b, s, 1) = W_{\lambda}(\tilde{b}, \tilde{s}, 1) + \chi = W_P - g(\alpha_P) + g(\alpha) - \lambda \sum_{i \in \mathcal{C}} \eta^i(\alpha, 0) + \chi,$$

where we denote $\chi = \lambda \sum_{i=1}^n (s^i - s_0^i)^+ + \lambda \sum_{i \in \mathcal{C}} (\eta^i(\alpha, 0) - b^i)^+$, and we have used Lemma 3.9 in the second equation. To show the first statement, it thus remains to show that $\chi \geq \chi_{\mathcal{C}}(\alpha)$.

For any bank $i \in \mathcal{C}$, let a_{-i} denote the response vector where every bank but bank i accepts the proposal. Set $\alpha_{-i} = \bar{\alpha}(b, s, a_{-i})$. Welfare losses in this response are equal to

$$\begin{aligned} W_{\lambda}(b, s, a_{-i}) &= W_{\lambda}(b, s, 1) - g(\alpha) + g(\alpha_{-i}) + \lambda \min(b^i, b_0^i) \\ &= W_P - g(\alpha_P) - g(\alpha) + g(\alpha_{-i}) - h_{\mathcal{C} \setminus \{i\}}(\alpha) + \chi. \end{aligned}$$

Solving for χ and using Condition 1 of Lemma 3.5, we obtain

$$\chi \geq W_N - W_P + g(\alpha_P) + g(\alpha) - g(\alpha_{-i}) + h_{\mathcal{C} \setminus \{i\}}(\alpha). \quad (37)$$

It follows from (35) that $\alpha \ell^i = (b^i - b_0^i)^+$, and hence

$$-\frac{\alpha_{-i} \ln(\alpha_{-i})}{\gamma} = -\frac{\alpha \ln(\alpha)}{\gamma} - (b^i - b_0^i)^+ \geq -\frac{\alpha \ln(\alpha)}{\gamma} - \bar{b}^i. \quad (38)$$

Multiplying (38) by $-\gamma$ and applying $g \circ z^{-1}$, we obtain $g(\alpha_{-i}) - g(\alpha) \leq g_{\alpha}(\bar{b}^i)$. In conjunction with (37), this yields

$$\chi \geq W_N - W_P + g(\alpha_P) + h_{\mathcal{C} \setminus \{i\}}(\alpha) - g_{\alpha}(\bar{b}^i). \quad (39)$$

Next, solving (37) for $g(\alpha_{-i}) - g(\alpha)$ and applying g_α^{-1} , we obtain

$$(b^i - b_0^i)^+ = \frac{\alpha_{-i} \ln(\alpha_{-i}) - \alpha \ln(\alpha)}{\gamma} \geq g_\alpha^{-1}(W_N - W_P + g(\alpha_P) + h_{\mathcal{C} \setminus \{i\}}(\alpha) - \chi).$$

Summing over all $i \in \mathcal{C}$ yields

$$\begin{aligned} -\frac{\alpha \ln(\alpha)}{\gamma} &= \sum_{i=1}^n ((s_0^i - s^i)^+ + (b^i - b_0^i)^+) \geq \sum_{i \in \mathcal{C}} (b^i - b_0^i)^+ \\ &\geq \sum_{i \in \mathcal{C}} g_\alpha^{-1}(W_N - W_P + g(\alpha_P) + h_{\mathcal{C} \setminus \{i\}}(\alpha) - \chi). \end{aligned} \quad (40)$$

Since $\chi_{\mathcal{C}}(\alpha)$ is the smallest value $\chi' \geq 0$ that satisfies (39) for all $i \in \mathcal{C}$ and (40), it follows that $\chi_{\mathcal{C}}(\alpha) \leq \chi$. This concludes the proof that $W_\lambda(b, s, a) \geq W_{\mathcal{C}}(\alpha)$.

Note that this lower bound holds with equality if and only if $\chi = \chi_{\mathcal{C}}(\alpha)$, i.e., Condition (iv) in Definition 3.2 is satisfied. It remains to show that (b, s) satisfies the other four conditions. We have already argued that Conditions (i) and (ii) are satisfied. Equation (35) implies that

$$\ell^i(b, s, a) = \frac{1}{\alpha} ((s_0^i - s^i)^+ + (b^i - b_0^i)^+). \quad (41)$$

It follows from (1) and (41) that Condition (iii) is satisfied. Finally, Condition 1 of Lemma 3.5 for $i \in \mathcal{C}$ implies that Condition (v) holds. This concludes the proof. \square

Lemma C.3 shows that welfare losses $W_{\mathcal{C}}(\alpha)$ are attained only by bail-ins in $\Xi(\mathcal{C}, \alpha)$. The following lemma shows that the converse is true as well if $\alpha \geq \frac{1}{e}$.

Lemma C.4. *For any \mathcal{C} and any $\alpha \geq \frac{1}{e}$, any $(b, s) \in \Xi(\mathcal{C}, \alpha)$ is a complete feasible bail-in proposal with $W_\lambda(b, s, 1) = W_{\mathcal{C}}(\alpha)$ that admits response vector $1 = (1, \dots, 1)$ in equilibrium. Moreover, if $W_{\mathcal{C}}(\alpha) < W_N$, then $1 = (1, \dots, 1)$ is an accepting equilibrium.*

Proof. Fix $(b, s) \in \Xi(\mathcal{C}, \alpha)$. It follows along the same lines as in the proof of Lemma G.1 that (b, s) is a complete feasible bail-in with $\bar{\alpha}(b, s, 1) = \alpha$. Condition (i) in Definition 3.2 implies that Condition 2 in Lemma 3.5 is satisfied for every bank $i \in \mathcal{C}$ in the response vector 1. It follows from Lemma 3.8 and Condition (iv) Definition 3.2 that $W_\lambda(b, s, 1) = W_{\mathcal{C}}(\alpha)$. Condition (v) in Definition 3.2 thus implies that Condition 1 of Lemma 3.5 is satisfied for every bank $i \in \mathcal{C}$. Therefore, an application of Lemma 3.5 shows that 1 is an equilibrium response. It is immediate that 1 is an accepting equilibrium if $W_{\mathcal{C}}(\alpha) < W_N$. \square

Lemma C.5 shows that the equilibrium bail-in contributors are the banks with the largest exposure to contagion effects.

Lemma C.5. *For any bail-in proposal (b, s) , let $\ell(b, s)$ denote the induced vector of liquidations when every bank accepts the proposal. For any vector ℓ , let $\mathcal{C}(\ell)$ be defined as in Theorem 3.10.*

Suppose that there exists \mathcal{C} such that in any subgame Pareto-efficient equilibrium, a bail-in from $\Xi(\mathcal{C}, \alpha)$ is implemented. Then $\mathcal{C} = \mathcal{C}(\ell(b, s))$ for any $(b, s) \in \Xi(\mathcal{C}, \alpha)$.

Proof. Let \mathcal{C} be such that in any subgame Pareto-efficient equilibrium, a bail-in from $\Xi(\mathcal{C}, \alpha)$ is implemented. Fix $(b, s) \in \Xi(\mathcal{C}, \alpha)$ and abbreviate $\ell = \ell(b, s)$. Suppose towards a contradiction that there exists a pair of banks $(i_0, j_0) \in \mathcal{C}^c \times \mathcal{C}$ such that $\eta^{i_0}(\alpha, \ell) > \eta^{j_0}(\alpha, \ell)$. Let $\tilde{\mathcal{C}} := \mathcal{C} \setminus \{j_0\} \cup \{i_0\}$ and define a bail-in (\tilde{b}, \tilde{s}) by setting $\tilde{b}^{i_0} = \eta^{i_0}(\alpha, \ell)$, $\tilde{s}^{i_0} = 0$, $\tilde{b}^{j_0} = 0$, $\tilde{s}^{j_0} = 0$, as well as $\tilde{b}^i = b^i$ and $\tilde{s}^i = s^i$ for any other bank $i \notin \{j_0\} \cup \{i_0\}$.

We will first show that (\tilde{b}, \tilde{s}) is a complete, feasible bail-in proposal. By definition of ℓ , the shortfall of any bank i in the bail-in (b, s) is $\alpha \ell^i$. Let $\tilde{\sigma}^i := (L^i + w^i + \tilde{b}^i - c^i - \tilde{s}^i - (\pi L)^i)^+$ denote the shortfall of bank i in bail-in (\tilde{b}, \tilde{s}) . Since $\tilde{b}^i = b^i$ and $\tilde{s}^i = s^i$ for every $i \notin \{i_0, j_0\}$, it follows that $\tilde{\sigma}^i = \alpha \ell^i$ for every such bank i . Since j_0 makes a positive net contribution $b^{j_0} - s^{j_0}$ to the bail-in (b, s) by Condition 1 of Lemma 3.5, it follows that $\tilde{\sigma}^{j_0} \leq (L^{j_0} + w^{j_0} + b^{j_0} - c^{j_0} - s^{j_0} - (\pi L)^{j_0})^+ = \alpha \ell^{j_0}$ with strict inequality if $\ell^{j_0} > 0$. The definition of $\eta(\alpha, \ell)$ in (16) implies that $\tilde{b}^{i_0} \leq (c^{i_0} + \alpha \ell^{i_0} + (\pi L)^{i_0} - w^{i_0} - L^{i_0})^+$, and hence $\tilde{\sigma}^{i_0} \leq \alpha \ell^{i_0}$ also for bank i_0 . We conclude that $\tilde{\sigma}^i \leq \alpha \ell^i \leq e^i$ for every bank i , hence (\tilde{b}, \tilde{s}) is a complete feasible bail-in proposal.

Since the total shortfall is smaller in (\tilde{b}, \tilde{s}) than in (b, s) , it follows that $\tilde{\alpha} := \alpha(\tilde{b}, \tilde{s}, 1) \geq \alpha$. Observe further that $\eta^{i_0}(\alpha, \ell) > \eta^{j_0}(\alpha, \ell) \geq b^{j_0} > 0$ implies $s^{i_0}(\alpha, \ell) = 0$ and hence $s^{i_0} = 0 = \tilde{s}^{j_0}$. It also implies that $\tilde{b}^{i_0} > b^{j_0}$, which yields

$$W_\lambda(\tilde{b}, \tilde{s}, 1) = W_\lambda(b, s, 1) - (\alpha - \tilde{\alpha}) \sum_{i=1}^n e^i - \lambda(\tilde{b}^{i_0} - b^{j_0}) < W_\lambda(b, s, 1).$$

Because 1 is an accepting equilibrium for (b, s) , this shows that $W_\lambda(\tilde{b}, \tilde{s}, 1) < W_N$.

For any $i \in \tilde{\mathcal{C}}$, let a_{-i} denote the response vector by the banks where every bank but i accepts the proposal. Observe that $W_\lambda(\tilde{b}, \tilde{s}, a_{-i_0}) = W_\lambda(b, s, a_{-j_0}) \geq W_N$ by Condition 1 of Lemma 3.5. For any $i \in \tilde{\mathcal{C}} \setminus \{i_0\}$, let $\tilde{\alpha}_{-i} = \tilde{\alpha}(\tilde{b}, \tilde{s}, a_{-i})$ and $\alpha_{-i} = \alpha(b, s, a_{-i})$ and observe that

$$-\frac{\tilde{\alpha}_{-i} \ln(\tilde{\alpha}_{-i})}{\gamma} + \frac{\alpha_{-i} \ln(\alpha_{-i})}{\gamma} = \sum_{j \neq i} \tilde{\sigma}^j - \sum_{j \neq i} \alpha \ell^j = \tilde{\sigma}^{i_0} + \tilde{\sigma}^{j_0} - \alpha(\ell^{i_0} + \ell^{j_0}) \leq 0. \quad (42)$$

Equation (42) implies that $\tilde{\alpha}_{-i} \geq \alpha_{-i}$. Moreover, since the difference in shortfall is the same as the difference of shortfalls between $(\tilde{b}, \tilde{s}, 1)$ and $(b, s, 1)$, it follows from concavity of $x \mapsto -x \ln(x)$ that $\tilde{\alpha}_{-i} - \alpha_{-i} \leq \tilde{\alpha} - \alpha$. This implies that

$$W_\lambda(b, s, a_{-i}) - W_\lambda(\tilde{b}, \tilde{s}, a_{-i}) \leq W_\lambda(b, s, 1) - W_\lambda(\tilde{b}, \tilde{s}, 1). \quad (43)$$

Define now a vector of subsidies $\hat{s} \geq \tilde{s}$ that burns additional welfare precisely equal to

$$\chi := \max_{i \in \mathcal{C}} (W_\lambda(b, s, a_{-i}) - W_\lambda(\tilde{b}, \tilde{s}, a_{-i})).$$

This can be attained either by awarding additional subsidies χ/λ to a bank $i \notin \mathcal{C}$ with $\ell^i = 0$ or

by awarding additional subsidies $\frac{1}{\lambda}(\chi + (z^{-1}(\ln(\tilde{\alpha})\tilde{\alpha} + \alpha\gamma\ell^i) - \tilde{\alpha})\sum_{i=1}^n e^i)$ to a bank $i \in \mathcal{C}$. By Condition 1 of Lemma 3.5 for bail-in (b, s) , we have $W_\lambda(\tilde{b}, \hat{s}, a_{-i}) \geq W_\lambda(b, s, a_{-i}) \geq W_N$, showing that Condition 1 of Lemma 3.5 is also satisfied in (\tilde{b}, \hat{s}) . Since $\alpha(\tilde{b}, \hat{s}, 1) \geq \tilde{\alpha} \geq \alpha$, it follows that also Condition 2 of Lemma 3.5 is satisfied in (\tilde{b}, \hat{s}) for every bank i . Finally, it follows from (43) that

$$W_\lambda(\tilde{b}, \hat{s}, 1) = W_\lambda(\tilde{b}, \tilde{s}, 1) + \chi \leq W_\lambda(b, s, 1) < W_N.$$

This shows that $a = (1, \dots, 1)$ is an accepting equilibrium for (\tilde{b}, \hat{s}) . Since no subset of accepting banks is an accepting equilibrium by Condition 2 of Lemma 3.5, it is the unique accepting equilibrium and hence also the unique subgame Pareto efficient continuation equilibrium by Lemma 3.7. Since (b, s) is a subgame Pareto efficient equilibrium outcome, the regulator has no profitable deviations from (\tilde{b}, \hat{s}) . This shows that (\tilde{b}, \hat{s}) is a subgame Pareto-efficient equilibrium outcome as well, contradicting the fact that contributions have to come from \mathcal{C} . We conclude that $C = \mathcal{C}(\ell)$. \square

Finally, we need one last technical result before we are able to prove Theorem 3.10.

Lemma C.6. *For any set of banks \mathcal{C} , the function $\chi_{\mathcal{C}}$ defined in Lemma A.1 is continuous on the interval $[\frac{1}{e}, 1]$. Hence, $W_{\mathcal{C}}$ is continuous as well.*

Proof. Fix an arbitrary set of banks \mathcal{C} . Since g , $\eta(\cdot, \ell)$, and $g_\alpha(x)$ are continuous in α , it follows straight from the definition of $\chi_{\mathcal{C}}^i$ in Lemma A.1 that $\chi_{\mathcal{C}}^i$ is continuous in α for each i . For continuity of $\hat{\chi}_{\mathcal{C}}(\alpha)$, let $f_{\mathcal{C}}(\alpha, \chi)$ denote the function on the right-hand side of (26). As we have shown in the proof of Lemma A.1, $f_{\mathcal{C}}(\alpha, \chi)$ is strictly decreasing in χ . By definition, $\hat{\chi}_{\mathcal{C}}(\alpha)$ is the smallest value $\chi \geq 0$ such that $f_{\mathcal{C}}(\alpha, \chi) \leq -z(\alpha)/\gamma$. On the set $O := \{\alpha \in [\frac{1}{e}, 1] \mid f_{\mathcal{C}}(\alpha, 0) \leq -z(\alpha)/\gamma\}$, it follows that $\hat{\chi}_{\mathcal{C}}(\alpha) = 0$. On the complement of O , we have $f_{\mathcal{C}}(\alpha, \hat{\chi}_{\mathcal{C}}(\alpha)) = -z(\alpha)/\gamma$ by continuity of $f_{\mathcal{C}}(\alpha, \chi)$ in χ . For any $\alpha \in O^c$, let $f_{\mathcal{C}}^{-1}(-\frac{z(\alpha)}{\gamma})$ denote the pre-image of $-\frac{z(\alpha)}{\gamma}$ under $f_{\mathcal{C}}(\alpha, \cdot)$. Since $\hat{\chi}_{\mathcal{C}}(\alpha)$ is the unique solution to (26), the pre-image is unique, meaning that $f_{\mathcal{C}}(\alpha, \cdot)$ is invertible. It follows that $\hat{\chi}_{\mathcal{C}}(\alpha) = f_{\mathcal{C}}^{-1}(-\frac{z(\alpha)}{\gamma})$ is continuous on O^c being the composition of continuous functions. Continuity of $f_{\mathcal{C}}$ and z implies that $\lim_{\alpha \in O^c} \hat{\chi}_{\mathcal{C}}(\alpha) = 0$ as $\alpha \in O^c$ approaches the border of O and hence $\hat{\chi}_{\mathcal{C}}(\alpha)$ is continuous everywhere. Finally, $\chi_{\mathcal{C}}$ is continuous being the maximum of continuous functions. Continuity of $W_{\mathcal{C}}$ now follows from the continuity of g and $\eta^i(\cdot, 0)$ for any $i \in \mathcal{C}$. \square

Proof of Theorem 3.10. If the threat fails to be credible, then it follows from Proposition 3.3 that the regulator will implement an optimal public bailout as given in Lemma 5.1, either by proposing it in the first stage or by choosing it in the third stage after an arbitrary proposal in the first stage.

Suppose, therefore, that the threat is credible. Since $W_{\mathcal{C}}$ is continuous by Lemma C.6, $W_{\mathcal{C}}$ attains a minimum on the interval $[\frac{1}{e}, 1]$. Let $A(\mathcal{C})$ denote the set of prices α that minimize $W_{\mathcal{C}}(\alpha)$. Let \mathcal{C}_* denote the set of banks \mathcal{C} that minimizes $\min_{\alpha} W_{\mathcal{C}}(\alpha)$. For a generic choice of model parameters, the functions $(W_{\mathcal{C}})_{\mathcal{C} \subseteq \{1, \dots, N\}}$ are all distinct, and hence \mathcal{C}_* is generically unique.

Let $\alpha_* := \max\{\alpha \in A(\mathcal{C}_*)\}$. By Lemma C.4, any bail-in proposal $(b, s) \in \Xi(\mathcal{C}_*, \alpha)$ for any $\alpha \in A(\mathcal{C}_*)$ admits equilibrium response $1 = (1, \dots, 1)$, and it attains welfare losses $W_{\mathcal{C}_*}(\alpha_*)$. It follows as a consequence of Lemma G.5 in the online appendix that $W_{\mathcal{C}_*}(\alpha_*) < W_N$, and hence the

response vector of unanimous acceptance is an accepting equilibrium for any $(b, s) \in \Xi(\mathcal{C}_*, \alpha)$ and any $\alpha \in A(\mathcal{C}_*)$ by Lemma C.4. By Condition 1 in Lemma 3.5, it is the unique accepting equilibrium. Since rejecting equilibria are subgame Pareto dominated by Lemma 3.7, the regulator is aware that any bail-in $(b, s) \in \Xi(\mathcal{C}_*, \alpha)$, for $\alpha \in A(\mathcal{C}_*)$, which he proposes in the first stage will be accepted in equilibrium. Because no incentive-compatible bail-in can attain lower welfare losses by Lemmas C.2 and C.3, the regulator’s only rational choice in stage 1 is to propose such a bail-in. Subgame Pareto efficiency then imposes that the regulator proposes a bail-in from $\Xi(\mathcal{C}_*, \alpha_*)$. Finally, Lemma C.5 shows that $\mathcal{C}_* = \mathcal{C}(\ell(b, s))$ for any $(b, s) \in \Xi(\mathcal{C}_*, \alpha_*)$ if \mathcal{C}_* is unique. \square

D Data Calibration Procedure

A total of 48 banks participated in the stress test of the EBA. Values of various banks’ balance sheet quantities are reported as of end 2017. For each bank, the EBA reports the exposures to other institutions, computed using an internal rating based (IRB) criterion as of end 2017. We take those exposures as a measure of the bank’s total claims A on all other banks in the network. Some of the smallest banks reported zero interbanking claims. We omit those from the analysis, leaving us with a total of 36 banks. To estimate interbank liabilities, we first compute the banks’ total liabilities as the difference between their total asset holdings and their equity value E , both of which are reported in the EBA data. We then assume that each bank has the same ratio of interbank to total liabilities. We compute this ratio by imposing that the sum of interbank liabilities across all banks equals the sum of interbank claims. Since most quantities in our model depend on c and w only through their difference $c - w$, we set $c = E + \max(E + L - A, 0)$ and $w = E + \max(A - E - L, 0)$ so that the equity value of each bank corresponds to that implied from the EBA data, and we can apply a shock of size $c^i \geq E^i$ to any bank to induce a fundamental default. All raw data and estimated model quantities are summarized in Table 1. We set $\lambda = 3$ and the recovery rate β to 60%. This value is in line with empirical estimates reported by Moody’s; see Footnote 13.

Finally, we discuss how we construct the sparse network π_s . We use an iterated greedy algorithm. In each step of the algorithm, we construct a ring network $j_1 \rightarrow j_2 \rightarrow \dots \rightarrow j_n \rightarrow j_1$ as follows: Given $j_1 \rightarrow \dots \rightarrow j_k$, the creditor of j_k is selected to be the bank with the smallest interbank claims among all banks in $\{j_{k+1}, \dots, j_n\}$ whose interbank claims exceed j_k ’s interbank liabilities. If such a bank exists, all of j_k ’s liabilities are assigned to that bank. If there exists no such bank, j_{k+1} is the bank with the largest interbank claims and we assign $\sum_i L^{j_{k+1}i}$ of j_k ’s liabilities to bank j_{k+1} , leaving the remainder of j_{k+1} ’s interbank liabilities to be assigned in the next iteration. Each ring starts with the bank whose unassigned interbank liabilities are the largest. This method is greedy because, for each considered bank, it assigns all its interbank liabilities to a single bank, if possible. An iterated construction using rings guarantees that the resulting network consists of only one connected component.
