Estimating Macroeconomic Models of Financial Crises: An Endogenous Regime-Switching Approach*

Abstract

We estimate a workhorse DSGE model with an occasionally binding borrowing constraint. First, we propose a new specification of the occasionally binding constraint, where the transition between the unconstrained and constrained states is a stochastic function of the leverage level and the constraint multiplier. This specification maps into an endogenous regime-switching model. Second, we develop a general perturbation method for the solution of such a model. Third, we estimate the model with Bayesian methods to fit Mexico's business cycle and financial crisis history since 1981. The estimated model fits the data well, identifying three crisis episodes of varying duration and intensity: the Debt Crisis in the early-1980s, the Peso Crisis in the mid-1990s, and the Global Financial Crisis in the late-2000s. These crisis episodes display sluggish and long-lasting build-up and recovery phases driven by plausible combinations of shocks.

Keywords: Financial Crises, Business Cycles, Endogenous Regime-Switching, Bayesian Estimation, Occasionally Binding Constraints, Mexico.

1 Introduction

The Global Financial Crisis triggered strong renewed interest in understanding the causes, consequences, and remedies of financial crises. In this context, dynamic stochastic general equilibrium (DSGE) models with occasionally binding financial frictions proved successful as laboratories to study the anatomy of both business cycles and crises, and to explore optimal policy responses to these dynamics. This success is because occasionally binding financial frictions are mechanisms that create amplification of regular business cycle dynamics. Structural estimation of these models is challenging, yet important for inference on key parameters governing financial frictions, counterfactual analysis, and structural real-time forecasts.

In this paper, we structurally estimate a model with an occasionally binding borrowing constraint. We make three main contributions. First, we propose a new specification of the occasionally binding collateral constraint. Second, we develop a perturbation solution method suitable for solving models like ours in a way that permits likelihood-based estimation. Third, we focus on one particular type of crisis, the so-called sudden stop in international capital flows, and apply the proposed approach to the estimation of a medium-scale workhorse DSGE model of such crises, investigating sources and frictions of business cycles and crises in Mexico since 1981.

As a first step, we propose a new formulation of occasionally binding constraint models. Our set up has two states or regimes: in the first, limited leverage amplifies regular shocks and gives rise to financial crises episodes; in the second, access to financing is unconstrained and the economy displays regular business cycles. In our specification, however, the transitions between the two regimes depend on a *range* rather than a *unique* level of leverage, with endogenous switching probabilities that depend on the borrowing capacity and the multiplier associated with the leverage constraint. This formulation maps the model with an occasionally binding leverage constraint written as inequality into an endogenous regime-switching model. The paper focuses on a particular friction and type of crisis, the so called sudden stop in capital flows, but the proposed specification has broader applicability to other types of occasionally binding constraints.

Next, we develop a perturbation-based solution method for solving the endogenous regime-switching model. The perturbation method is fast enough to permit likelihood-based estimation, is readily scalable to models larger than the one we estimate in this paper, displays typical levels of accuracy. We also show analytically that to capture the effects of endogenous transition probabilities on the policy functions characterizing optimal behavior, and hence precautionary behavior, it is necessary to approximate the model solution at least to the second-order, and that these effects would be missed by linear approximations. As

2

with our first contribution, the solution method that we develop can be used with a wide range of endogenous regime-switching models.

Finally, we apply our borrowing constraint specification and solution method by performing Bayesian estimation of a workhorse small open-economy model that characterizes both financial crises and business cycles in Mexico. While our application focuses on an emerging market economy, our specification can be applied to the formulation and estimation of other model settings with occasionally binding constraints. For example, the approach that we propose could be applied to the formulation and estimation of models of occasionally binding credit frictions, housing constraints, banking with asymmetric information, downward wage rigidity, the zero lower bound, or a SIR-macro model in which the probability of being infected depends on agents' decisions.

Figure 1 plots two critical variables in our application to Mexico: the current account balance as a share of GDP and the quarterly real GDP growth in deviation from the sample mean. The figure illustrates the regular fluctuations in the data as well as multiple episodes of large current account reversals and persistent output growth declines. Large current account reversals and output drops of heterogeneous size and persistence are the two main empirical features commonly associated with sudden stops in capital flows, not only in Mexico but also in many other emerging markets exposed to volatile capital flows. In this paper, we focus on the challenge of fitting a structural model to Mexico's business cycle and sudden stop history.

Despite the econometric challenges in characterizing data like those displayed in Figure 1, our estimated model fits Mexico's business cycles and sudden stop episodes well, and does not rely on large shocks to explain crises but instead lets the economic structure of the model explain those events. It produces business cycle statistics that match the second moments of the data and provides evidence on the relative importance of different shocks. Most importantly, our new specification of the collateral constraint identifies crisis episodes and dynamics of varying duration and intensity, consistent with evidence not only of large economic dislocation during financial crises but also sluggish build-up and recovery phases surrounding them (Cerra and Saxena, 2008; Reinhart and Rogoff, 2009; Boissay et al., 2016).

In particular, the estimated model identifies three financial crises: the Debt Crisis from 1981:Q3 to 1983:Q2, the Mexican peso crisis commonly referred to as the "Tequila crisis" from 1994:Q1 to 1996:Q1, and the spillover effect from the Global Financial Crisis from 2008:Q4 to 2009:Q3. The identified crisis episodes align well with a purely empirical notion of financial crisis in Mexico (Reinhart and Rogoff, 2009) and display duration about twice as long as the crisis peaks previously identified as sudden stops (Cerra and Saxena, 2008). The model-simulated dynamics of crisis episodes indicate that they are preceded by slowly

unfolding booms and followed by economic stagnation, and are not only driven by a favorable external environment that suddenly reverses, but also domestic factors such as technology and demand shocks. We also show that different shocks matter more for different historical crisis episodes, as well as different phases of a given crisis episode.

Related Literature Our paper is connected to several strands of literature. The closest is the literature on likelihood-based estimation of Markov switching DSGE models initiated by the seminal contribution of Bianchi (2013), and applied in Bianchi and Ilut (2017) and Bianchi et al. (2018). Our algorithm differs in two key respects. First, our regime-switching transition matrix allows for endogenous switching. Second, conditional on the regime, we have a second order solution, so we employ the Sigma Point Filter to evaluate the likelihood function in place the modified Kalman filter in Bianchi (2013). In the literature on Markov-switching DSGE models, our paper builds upon the method developed by Foerster et al. (2016), who developed perturbation methods for the solution of exogenous regime-switching models. The perturbation approach that we propose allows for second- and higher-order approximations that go beyond the linear models studied by Davig and Leeper (2007) and Farmer et al. (2011). In fact, we show that at least a second-order approximation is necessary

4

in order to capture the effects of the endogenous switching.

The paper is also related to the literature that focuses on solving endogenous regime-switching models. Davig and Leeper (2008), Davig et al. (2010), and Alpanda and Ueberfeldt (2016) all consider endogenous regime-switching but employ computationally costly global solution methods that hinder likelihood-based estimation. Lind (2014) develops a regime-switching perturbation approach for approximating non-linear models, but it requires repeatedly refining the points of approximation and hence it is not suitable for estimation purposes. Maih (2015) and Barthlemy and Marx (2017) also propose perturbation methods for endogenous switching models, but employ a technique that approximates around regime-dependent steady states, which may not be a suitable choice given the relatively rare frequency of crises. In contrast, our perturbation method uses a single approximation point in the area of the state-space where the economy spends most of the time.

Here, our paper relates also to Guerrieri and Iacoviello (2015), who develop OccBin, a set of procedures for the solution of models with occasionally binding constraints. OccBin is a certainty equivalent solution method that captures non-linearities but not precautionary effects, which are a critical feature of models with occasionally binding collateral constraints.[1] A key feature of our approach is to preserve precautionary saving effects, as agents in the model adjust their behavior due to the presence of the constraint even when the constraint does not bind, and vice versa.

More generally, our paper relates to the now large literature on the Bayesian estimation of DSGE models (for example, Schorfheide, 2000; Otrok, 2001; Smets and Wouters, 2007; Iacoviello and Neri, 2010). We extend that successful approach to models with occasionally binding collateral constraints, which have become the benchmark for normative analysis of macro-prudential optimal policy. Welfare-base analysis of optimal macroprudential policies with occasionally binding constraints depends critically on calibrations assumptions and collateral constraint formulations. Structural estimation of these parameters and likelihood based model validation can discipline model formulation, which in turn is critical for normative policy recommendations. In this respect, our paper is related to the estimation exercise in Bocola (2016) that is accomplished while solving the model with global methods. However, this is made possible by first estimating the model outside the crisis, and then appending an estimate of the crisis in a second step. While this procedure does not matter for the specific application in Bocola (2016), it is not necessarily applicable more generally. Our approach permits joint estimation of the model inside and outside the crises and is potentially scalable to larger and more complex models, while maintaining a satisfactory level of accuracy

---

[1]Cuba-Borda et al. (2019) study how the solution method and likelihood misspecification interact and possibly compound each other.

relative to global solution methods.

The specification of the constraint that we propose and the accompanying perturbation solution method could be easily applied to models with occasionally binding zero-lower bound on interest rates (for example, Adam and Billi, 2007; Aruoba et al., 2018; Atkinson et al., 2018). Existing methods for the estimation of such models may limit scalability due to computational costs (Gust et al., 2017). Moreover, the occasionally binding zero lower bound is not comparable to the kind of constraints with endogenous collateral value that we estimate in this paper and is used in the normative literature on macroprudential policies (Benigno et al., 2013, 2016). Indeed, endogenous collateral valuation features different amplification mechanisms and entails additional computational complexities (Bianchi and Mendoza, 2018; Devereux et al., 2019).

The application of the methodology that we propose relates to the literature on emerging market business cycles, which includes Aguiar and Gopinath (2007), Mendoza (2010), Garcia-Cicco et al. (2010), Fernandez-Villaverde et al. (2011), and Fernandez and Gulan (2015), among others. Encompassing most shocks previously considered, we include in our analysis technology, preference, expenditure, interest rate, and terms of trade shocks. Relative to Mendoza (2010), we provide a Bayesian estimation of the model and consider a wider set of structural shocks, finding that some of the estimated values of the parameters that are not easily calibrated to the stylized facts of the data differ substantially. Relative to Garcia-Cicco et al. (2010), we evaluate empirically the relative importance of interest rate shocks in an fully non-linear framework, with a more articulated specification of the financial frictions driving amplification. Consistent with Fernandez and Gulan (2015) and Ates and Saffie (2016), we can fit ergodic second moments of the data well with uncorrelated shocks, but specific combinations of shocks are associated with crisis dynamics.

The rest of the paper is organized as follows. Section 2 describes the model and discusses the proposed formulation of the collateral constraint. Section 3 presents our perturbation solution method for endogenous regime-switching models. Section 4 describes the Bayesian estimation procedure. Section 5 reports the estimation results on parameters, model fit, and business cycle properties. Section 6 presents results on financial crises. Section 7 concludes. The Appendices include technical details and additional empirical results.

2   The Model

The model is a medium scale, workhorse framework for the analysis of business cycles and sudden stop crises in emerging market economies. The core of the model is as in Mendoza (2010), although we consider a larger set of shocks as in Garcia-Cicco et al. (2010). It features

6

a small, open, production economy with an occasionally binding collateral constraint, that is subject to temporary productivity, intertemporal preference, expenditure, interest rate, and terms of trade shocks.[2] Due to the occasionally binding nature of the constraint, this framework can account not only for normal business cycles, but also key aspects of financial crises in both emerging markets and advanced economies. While our application focuses on one particular type of crisis, the so called sudden stop in capital flows, our framework is generally applicable to other macroeconomic models with occasionally binding frictions and crises (e.g., , Kiyotaki and Moore, 1997; Iacoviello, 2005; Gertler and Karadi, 2011; Jermann and Quadrini, 2012; Liu et al., 2013; Gertler and Kiyotaki, 2015; Bocola, 2016; Schmitt-Grohe and Uribe, 2016; Boissay et al., 2016; Eichenbaum et al., 2020). In the rest of this section, we discuss the representative household-firm and the borrowing constraint specification that is novel. The formal definition of the equilibrium and the full set of equilibrium conditions are reported in Appendix A.

2.1 Preferences, Constraints, and Shock Processes

There is a representative household-firm that maximizes the following utility function

$$U \equiv \mathbb{E}_0 \sum_{t=0}^{\infty} \left\{ d_t \beta^t \frac{1}{1-\rho} \left(C_t - \frac{H_t^\omega}{\omega} \right)^{1-\rho} \right\}, \tag{1}$$

where C_t denotes consumption, H_t the supply of labor, and d_t an exogenous and stochastic preference shock specified below. Households choose consumption, labor, capital K_t, imported intermediate inputs V_t given an exogenous stochastic relative price P_t also specified below, and holdings of real one-period international bonds, B_t. Negative values of B_t indicate borrowing from abroad. The household-firm faces the following budget constraint:

$$C_t + I_t + E_t = Y_t - \phi r_t \left(W_t H_t + P_t V \right) - \frac{1}{(1+r_t)} B_t + B_{t-1}, \tag{2}$$

where Y_t is gross domestic product given by

$$Y_t = A_t K_{t-1}^\eta H_t^\alpha V_t^{1-\alpha-\eta} - P_t V_t. \tag{3}$$

---

[2]We do not consider permanent technology shocks of the type analyzed by Aguiar and Gopinath (2007) because these long-run components cannot be estimated precisely over samples periods of length comparable to ours. Moreover, Garcia-Cicco et al. (2010) and Miyamoto and Nguyen (2017) also find that the permanent technology shock is not quantitatively important in frameworks with financial frictions like ours in the case of Mexico.

Here, A_t denotes the exogenous and stochastic level of technology. E_t is an exogenous and stochastic expenditure process possibly interpreted as a fiscal or net export shock as in Garcia-Cicco et al. (2010). The term $\phi r_t (W_t H_t + P_t V_t)$ describes a working capital constraint, stating that a fraction of the wage and intermediate good bill must be paid in advance of production with borrowed funds. The relative price of labor and capital are given by W_t and q_t, respectively, both of which are endogenous market prices, but taken as given by the individual household-firm. Gross investment, I_t, is subject to adjustment costs as a function of net investment:

$$I_t = \delta K_{t-1} + (K_t - K_{t-1}) \left(1 + \frac{\iota}{2}\left(\frac{K_t - K_{t-1}}{K_{t-1}}\right)\right). \tag{4}$$

Household-firms can borrow in international markets issuing one-period bonds that pay a market or country net interest rate r_t. The country interest rate between period t and $t+1$, r_t, has three components: an exogenous persistent component, an exogenous transitory component, and for technical reasons, a small endogenous component that depends on the level of debt. Thus, the country interest rate is given by

$$r_t = r_t^* + \sigma_r \varepsilon_{r,t} + \psi_r \left(e^{\bar{B} - B_t} - 1\right), \tag{5}$$

where the persistent exogenous component, r_t^*, follows the process

$$r_t^* = (1 - \rho_{r^*})\bar{r}^* + \rho_{r^*} r_{t-1}^* + \sigma_{r^*} \varepsilon_{r^*,t}, \tag{6}$$

with $\varepsilon_{r^*,t}$ and $\varepsilon_{r,t}$ i.i.d. $N(0,1)$, and σ_{r^*} and σ_r denoting parameters that control the variance of the two components.[3]

As Mendoza (2010) notes, in our model, the household-firm also faces a endogenous external financing premium on debt (EFPD), measured by the difference between the effective real interest rate, which corresponds to the intertemporal marginal rate of substitution in consumption, $r_t^h = \mu_t / E_t[\mu_{t+1}]$, and the market interest rate, r_t. In fact, the Euler equation for b_t, $\mu_t = \lambda_t + \beta (1 + r_t) \mathbb{E}_t \mu_{t+1}$, can be rearranged to show that $EFPD = \mathbb{E}_t[r_t^h - r_t] = \lambda_t / \beta E_t[\mu_{t+1}]$, where μ_t is the Lagrange multiplier on the budget constraint and λ_t is the multiplier on the collateral constraint to be introduced shortly. Because of this model feature, the endogenous interest rate component of r_t, $\psi_r \left(e^{\bar{B} - B_t} - 1\right)$ in equation (5) will be calibrated to serve the sole purpose of inducing independence of the

---

[3]While contemporaneous movements in $\varepsilon_{r^*,t}$ and $\varepsilon_{r,t}$ are not identified separately in equations (5) and (6), $\varepsilon_{r,t}$ will be identified in the data because of differences in persistence. Including both types of shocks helps fitting the observable counterpart variable in estimation.

model steady state from initial conditions, as in Schmitt-Grohe and Uribe (2003), by setting ψ_r to a very small value. In addition, we do not impose any correlation between the innovations to the interest rate process and the productivity process specified below.

The remaining exogenous processes for the preference shock d_t, the temporary technology shock A_t, the shock to the relative price of intermediate goods P_t, and the domestic expenditure shock E_t, are specified as follows:

$$\log d_t = \rho_d \log d_{t-1} + \sigma_d \varepsilon_{d,t}, \tag{7}$$

$$\log A_t = (1 - \rho_A) A^* + \rho_A \log A_{t-1} + \sigma_A \varepsilon_{A,t}, \tag{8}$$

$$\log P_t = (1 - \rho_P) P^* + \rho_P \log P_{t-1} + \sigma_P \varepsilon_{P,t}, \tag{9}$$

$$\log E_t = (1 - \rho_E) E^* + \rho_E \log E_{t-1} + \sigma_E \varepsilon_{E,t}, \tag{10}$$

where the starred variables and the $\rho_{\cdot}$ coefficients denote the unconditional mean values and the persistence parameters of the processes, $\varepsilon_{\cdot,t}$ are assumed i.i.d. $N(0,1)$ innovations, and the $\sigma_{\cdot,t}$ parameters control the size of the process variances.[4]

2.2 The Occasionally Binding Borrowing Constraint: An Endogenous Regime-Switching Specification

As in traditional models with occasionally binding inequality constraints, the economy fluctuates between two states or regimes. In one state, denoted $s_t = 1$ and called the binding or constrained regime, the following constraint on total borrowing binds strictly:

$$\frac{1}{(1+r_t)} B_t - \phi (1+r_t) (W_t H_t + P_t V_t) = -\kappa q_t K_t, \tag{11}$$

with λ_t denoting the corresponding multiplier. Total debt includes borrowing for consumption smoothing plus working capital for the purchase of intermediate inputs and labor for production. Limited working capital constraints the supply response of the economy to shocks in the constrained regime. In the other state, denoted $s_t = 0$ and called the nonbinding or unconstrained regime, the total borrowing limit is slack and $\lambda_t = 0$. Thus lenders finance all desired borrowing, and the only constraint is the natural debt limit.

Given these two regimes representing the occasionally binding nature of the borrowing

---

[4]The stochastic volatility features of emerging economies data as in (Fernandez-Villaverde, Guerron-Quintana, Rubio-Ramirez, and Uribe, 2011) could be allowed for by introducing regime-switching in the the volatilities of the shocks processes. While possible, we do not allow for regime-switching either in the intercepts or the volatilities of the shocks processes, as we want the collateral constraint to drive regime-switching, rather than shifts in the stochastic processes.

constraint, we characterize the transition between them *stochastically* in the sense that, for given values of capital, bond holding, and exogenous processes, there is an *endogenous* probability of switching between the regimes. This formulation contrasts with the *deterministic* relation between leverage and the regime for given values of endogenous and exogenous state variables in a traditional occasionally binding specification. Namely, we assume that the probabilities of switching from one regime to the other follow a logistic distribution as in Bocola (2016), where the economy's transition between a default and non-default state is also a logistic function of a restricted subset of the endogenous state variables of the model.[5]

Specifically, we define the "borrowing cushion," B_t^*, as the distance of total actual borrowing from the debt limit:

$$B_t^* = \frac{1}{(1+r_t)} B_t - \phi (1 + r_t) (W_t H_t + P_t V_t) + \kappa_t q_t K_t, \tag{12}$$

so that when the borrowing cushion is small, total borrowing is high relative to the value of collateral, and leverage is high. We then assume that the transition from the non-binding to the binding regime depends on B_t^*:

$$\Pr\left(s_{t+1} = 1 | s_t = 0, B_t^*\right) = \frac{\exp\left(-\gamma_0 B_t^*\right)}{1 + \exp\left(-\gamma_0 B_t^*\right)}. \tag{13}$$

Thus, the likelihood that the constraint binds in the *following* period depends on the size of the borrowing cushion in the *current* period.[6] The parameter γ_0 controls the steepness of the logistic function, determining the sensitivity of the probability of switching regime to the size of the borrowing cushion. When γ_0 is positive, as the cushion declines the probability of switching to the binding regime increases. Note here that, for certain draws from the logistic function, the borrowing cushion could be negative but the economy could still be in the non-binding regime.

Similarly, when the constraint binds, the transition probability to the non-binding regime is a logistic function of the Lagrange multiplier, λ_t:

$$\Pr\left(s_{t+1} = 0 | s_t = 1, \lambda_t\right) = \frac{\exp\left(-\gamma_1 \lambda_t\right)}{1 + \exp\left(-\gamma_1 \lambda_t\right)}. \tag{14}$$

The probability of switching back from the constrained to the unconstrained regime, there-

---

[5]Kumhof et al. (2015) also use a logistic function to model the transition to a default regime in the context of a positive analysis of the relation between financial crises and inequality. Davig, Leeper, and Walker (2010) and Bi and Traum (2014) use it to study the macroeconomic consequences of fiscal limits.

[6]As Appendix C shows, this timing difference with respect to models with traditional specifications of the occasionally borrowing constraint does not affect its positive properties as the behavior of the economy is essentially the same as in Mendoza (2010).

fore, depends on the shadow value of the economy's desired borrowing relative to the limit set by the collateral constraint. As in the case of a switch from the constrained to constrained regime, the parameter γ_1 affects the sensitivity of this probability to the value of the multiplier. When γ_1 is positive, as the multiplier declines, the probability of exiting the binding regime increases. As in the non-binding regime, for certain draws from the logistic, it is possible that the desired level of borrowing is less than the level forced upon the economy by the binding constraint and this will manifest itself with a negative collateral constraint multiplier.[7]

Putting equations (13) and (14) together, the regime-switching model has the following endogenous transition matrix

$$\mathbb{P}_t = \left[\begin{array}{cc} 1 - \frac{\exp(-\gamma_0 B_t^*)}{1+\exp(-\gamma_0 B_t^*)} & \frac{\exp(-\gamma_0 B_t^*)}{1+\exp(-\gamma_0 B_t^*)} \\ \frac{\exp(-\gamma_1 \lambda_t)}{1+\exp(-\gamma_1 \lambda_t)} & 1 - \frac{\exp(-\gamma_1 \lambda_t)}{1+\exp(-\gamma_1 \lambda_t)} \end{array} \right]. \tag{15}$$

Agents have full information with rational expectations about these transition probabilities that, in general equilibrium, are affected by all endogenous variables in the model.

2.3 Remarks on the Endogenous Regime-Switching Specification

A few remarks are useful on how our stochastic formulation of the borrowing constraint works and differs relative to the typical inequality formulation used in the literature.

First, in our setup, agents in the non-binding regime know that higher leverage increases the probability of switching to the binding regime, and vice-versa. Critically, this knowledge preserves the interaction in agents' behavior between regimes and gives rise to precautionary behavior, distinguishing this class of models from those in which financial frictions are always binding or are approximated with solution methods that eliminate the interactions across regimes as in Guerrieri and Iacoviello (2015). One could certainly consider a wider range of variables governing the regime transition. Our choice here, as in Bocola (2016), reflects the need to adopt a parsimonious representation. As we shall see, however, the specification proposed allow us to identify all parameter of interest and produces good model fit of the data with small shocks.

Second, as we have already noted, for certain draws of the regime state from the logistic distribution, the borrowing cushion and multiplier can take negative values in our specification of the occasionally binding constraint. This has the important implication that the build

---

[7]By construction, the transition probabilities equal 0.5 when their arguments are zero. This assumption can be easily relaxed by introducing a constant into the arguments of equations (13-14). However, preliminary estimates allowing for such degree of freedom suggested that these parameters were effectively zero. For ease of presentation, we omitted them from the beginning of the analysis.

up to, or the duration of, a financial crisis can be more persistent than in traditional models. As a consequence, our model can account for crisis episodes with varying dynamics and durations. For example, negative values of the borrowing cushion B_{t-1}^* in the non-binding regime are possible if the probability of a switch to a binding regime is elevated, but the switch has not been drawn yet, prolonging the boom phase and postponing the beginning of the crisis episode. Conversely, the economy can switch into the binding regime even if the borrowing cushion in the current period is still positive, anticipating the beginning of a crisis. The same logic applies to a probabilistic exit from the binding regime that depends on the multiplier λ_t. The economy might be stuck in the constrained regime past the time when the collateral constrained multiplier turned negative, extending the duration of the crisis. In fact, in this case, the economy may be "forced" to borrow a larger than desired amount until a non-binding realization of the regime is drawn. Conversely, despite positive values of the multiplier, the economy may end up exiting the binding regime early.

This important model property is consistent with a growing body of microeconomic evidence suggesting that a deterministic specification of the switch between regimes in models with occasionally binding collateral constraints may not accurately capture lending and borrowing behaviors at the household and firm or bank level. For example, Chodorow-Reich and Falato (2017) and Greenwald (2019) show that loan covenants are applied smoothing over time and are frequently violated, triggering renegotiation rather than suddenly cutting off borrowers from funding once activated. Campello et al. (2010) also provide survey information on the behavior of financially constrained firms, and Ivashina and Scharfstein (2010) examine loan level data, showing that firms draw down pre-existing credit lines in order to satisfy their liquidity needs to avoid hitting borrowing limits. In emerging market economies, official reserves play a similar liquidity role. Thus, in practice, collateral constraints bind for a range of leverage ratios rather than at any particular level as in model with inequality constraints, consistent with the macroeconomic empirical evidence of Jorda et al. (2013), who show that the exact level of leverage at which a crisis occurs varies considerably across crisis episodes.[8]

Third, our stochastic specification nests a deterministic case in which regime switching is triggered with probability 1 by a unique level of leverage. Moreover, we show in Appendix C that the numerical solution of our model is not distinguishable from its inequality counterpart, while at the same time offering a dramatically improved trade off between accuracy in terms of Euler equation errors and speed in terms of solution time.

Fourth and finally, as other specifications of occasionally binding collateral constraints in

---

[8]The notion of "debt intolerance" discussed by Reinhart and Rogoff (2009) and credit surface of Fostel and Geanakoplos (2015) also are consistent with our stochastic specification.

the literature (e.g., Bianchi, 2011; Schmitt-Grohe and Uribe, 2020; Farhi and Werning, 2020), our formulation is not derived as an equilibrium outcome of a fully specified contracting environment. Our specification however could be derived by generalizing existing contract environments. The traditional inequality formulation of our borrowing constraint,

$$\frac{1}{(1 + r_t)} B_t - \phi (1 + r_t) (W_t H_t + P_t V_t) \geq -\kappa q_t K_t. \tag{16}$$

can be derived as an implication of incentive compatibility constraints on borrowers if limited enforcement prevent lenders from collecting more than a fraction κ_t of the value of the assets owned by a defaulting borrower as for instance discussed in Bianchi and Mendoza (2018). An endogenous transition between the two regimes associated with this constraint could be derived in a standard costly state verification framework (Bernanke and Gertler, 1989). For example, Matsuyama (2007) shows how borrower net worth causes endogenous switching between investment projects with different productivity levels, which feeds back into borrower net worth. Martin (2008) shows that endogenous regime switches in financial contracts from pooling to separating and vice-versa leads to switching in lending standards between a "lax" and a "tight" regime.[9]

3   Solving the Endogenous Switching Model

This Section describes our solution method for endogenous regime-switching models. The model proposed in the previous section can in principle be solved using global methods, as for example in Davig et al. (2010). As we discuss in Appendix C, in the case of our application, with two endogenous and five exogenous state variables, the regime indicator, plus six exogenous shocks, using a global solution method would be extremely time consuming, and it would quickly become prohibitive with larger modes, precluding likelihood-based estimation. Instead, we solve the model using a perturbation approach, which allows for an accurate approximation that is fast enough to permit estimation and potentially applicable to larger frameworks beyond our medium-scale model. We now describe how to implement occasionally binding constraints represented as endogenous regime switching, the approximation point and how to define a steady state in this setup, and the Taylor-series expansions. We then discuss the importance of approximating at least to a second-order in our framework. The competitive equilibrium of the endogenous regime-switching model is defined formally in Appendix A. The derivations of the Taylor-series expansions and other details of

---

[9]Heterogeneous agent models with financial frictions imposed at the individual level could also be consistent with a stochastic specification of the switching between regimes.

Electronic copy available at: https://ssrn.com/abstract=3472296

the solution method are reported in Appendix B.

3.1   The Regime-Switching Slackness Condition

A critical step in applying our perturbation methods to the model above, is to ensure the that the two variables B_t^* and λ_t are zero if the economy is in the relevant regime: $\lambda_t = 0$ in the non-binding regime, and $B_t^* = 0$ in the binding regime. This step ensures that the slackness condition $B_t^* \lambda_t = 0$ always holds. To implement this and be consistent with regime-switching DSGE models in which the *parameters* are the model objects that change state, we define two auxiliary regime-dependent parameters, $\varphi(s_t)$ and $\nu(s_t)$, such that $\varphi(0) = \nu(0) = 0$, and $\varphi(1) = \nu(1) = 1$.[10] Next, we introduce the following regime-switching slackness condition:

$$\varphi(s_t) B_{ss}^* + \nu(s_t) (B_t^* - B_{ss}^*) = (1 - \varphi(s_t)) \lambda_{ss} + (1 - \nu(s_t)) (\lambda_t - \lambda_{ss}), \tag{17}$$

where B_{ss}^* and λ_{ss} are the steady state borrowing cushion and collateral constraint multiplier, respectively, defined more precisely below. It is now easy to see from equation (17) that, as desired, $\lambda_t = 0$ when $s_t = 0$, and $B_t^* = 0$ when $s_t = 1$, always satisfies the slackness condition $B_t^* \lambda_t = 0$ characterizing the representative household-firm's optimization problem. Yet, given a regime s_t, equation (17) remains continuously differentiable for any value of B_t^* or λ_t, as no inequality constraint is imposed.

Technically, equation (17) "preserves" information in the perturbation approximation that we introduce in Section 3.3, since, at first order, both variables B_t^* and λ_t are constant at zero in the respective regimes. The use of the regime-dependent switching parameters, $\varphi(s_t)$ and $\nu(s_t)$, follows from the Partition Principle of Foerster et al. (2016), which separates parameters based upon whether they affect the steady state or not. Intuitively, $\varphi(s_t)$ captures the *level* of the economy changing across regimes (e.g., the level of capital is lower when the constraint binds), while $\nu(s_t)$ captures the dynamic responses differing across regimes (e.g., the response of investment to shocks changes when the constraint binds).

3.2   Defining the Steady State

Given the regime-switching slackness condition (17), we define a steady state in this setting as a state in which all shocks have ceased and the regime-switching variables that affect the level of the economy ($\varphi(s_t)$) take the *ergodic mean* associated with the steady state transition

---

[10]In our model these parameters coincide with the regime-switching indicator variable s_t, but in more general settings they may not. The notation provides a general formulation of the modified slackness condition that is applicable to other setups. See, for example, the discussion of our stochastic specification in the context of other model settings in Binning and Maih (2017).

matrix:

$$\mathbb{P}_{ss} = \begin{bmatrix} 1 - \frac{\exp(-\gamma_0 B_{ss}^*)}{1+\exp(-\gamma_0 B_{ss}^*)} & \frac{\exp(-\gamma_0 B_{ss}^*)}{1+\exp(-\gamma_0 B_{ss}^*)} \\ \frac{\exp(-\gamma_1 \lambda_{ss})}{1+\exp(-\gamma_1 \lambda_{ss})} & 1 - \frac{\exp(-\gamma_1 \lambda_{ss})}{1+\exp(-\gamma_1 \lambda_{ss})} \end{bmatrix}. \tag{18}$$

Since this matrix depends on the steady state level of the borrowing cushion and the multiplier, B_{ss}^* and λ_{ss}, which in turn depend upon the ergodic mean of the regime-switching parameter $\varphi(s_t)$, such a steady state is the solution of a fixed point problem that is described in more detail in Appendix B.

More specifically, consider the model regime-specific parameters defined above and distinguish between $\varphi(s_t)$, which affect the level behavior of the economy, and $\nu(s_t)$, which affect only its dynamics with no effects on the steady state. Then denote with $\xi = [\xi_0, \xi_1]$ the ergodic vector of $\mathbb{P}_{ss}$. Next, apply the Partition Principle of Foerster et al. (2016) to focus only on parameters that affect the level of the economy, and write their ergodic mean of $\varphi(s_t)$, denoted $\bar{\varphi}$, as

$$\bar{\varphi} = \xi_0 \varphi(0) + \xi_1 \varphi(1). \tag{19}$$

Defining the steady state as the state in which the auxiliary parameter $\varphi(s_t)$ is at its ergodic mean value $\bar{\varphi}$ implies that the approximation point constructed is a weighted average of the steady states of two separate models: a model in which only the non-binding regime occurs, and one in which only the binding regime occurs. How close our approximation point is to each of these two other steady states, therefore, depends on the frequency of being in each of the two regimes. As in our application episodes of binding regime have limited duration, the ergodic mean is a natural candidate as the perturbation point. Given the nature of our application with slow-moving capital and debt state variables, this perturbation point will be in the area of the state space in which the economy operates most frequently. In fact, since the binding regime tends to be self-limiting—that is, being in the binding regime causes the economy to reduce leverage and hence switch back to the non-binding regime—the economy will rarely reach the area around the steady state of the "binding regime only."[11]

3.3 The Solution and Its Properties

Equipped with the steady state of the endogenous regime-switching economy, we construct a second-order approximation to the policy functions by taking derivatives of the equilibrium conditions. We relegate details of these derivations to the Appendix B, but here we provide

---

[11]Alternative methods for finding solutions to endogenous regime-switching models, such as Maih (2015) and Barthlemy and Marx (2017), propose using regime-dependent steady states as multiple approximation points. Such a strategy would not be suitable for our purposes because the binding regime steady state is a poor approximation point given that the regime is infrequent and usually of shorter duration than normal cycles of expansions and contractions.

a summary.

For each regime s_t, the policy functions of our model take the form

$$\mathbf{x}_t = h_{s_t}\left(\mathbf{x}_{t-1}, \varepsilon_t, \chi\right), \qquad \mathbf{y}_t = g_{s_t}\left(\mathbf{x}_{t-1}, \varepsilon_t, \chi\right), \qquad (20)$$

where $\mathbf{x}_t$ denotes predetermined variables, $\mathbf{y}_t$ non-predetermined variables, $\varepsilon_{\mathbf{t}}$ the set of shocks, and χ a perturbation parameter such that when $\chi = 1$ the fully stochastic model results and when $\chi = 0$ the model reduces to the non-stochastic steady state defined above. Using these functional forms, we can express the equilibrium conditions conditional on regime s_t as

$$\mathbb{F}_{s_t}\left(\mathbf{x}_{t-1}, \varepsilon_t, \chi\right) = 0. \qquad (21)$$

We then stack the regime-dependent conditions for $s_t = 0$ and $s_t = 1$, denoting the resulting system of equations with $\mathbb{F}\left(\mathbf{x}_{t-1}, \varepsilon_t, \chi\right)$, and successively differentiate with respect to $\left(\mathbf{x}_{t-1}, \varepsilon_t, \chi\right)$, evaluating them at the steady state. The systems

$$\mathbb{F}_{\mathbf{x}}\left(\mathbf{x}_{ss}, \mathbf{0}, 0\right) = 0, \quad \mathbb{F}_{\varepsilon}\left(\mathbf{x}_{ss}, \mathbf{0}, 0\right) = 0, \quad \mathbb{F}_{\chi}\left(\mathbf{x}_{ss}, \mathbf{0}, 0\right) = 0 \qquad (22)$$

can then be solved for the unknown coefficients of the first-order Taylor expansion of the policy functions in equation (20). Note here that since we are only approximating the decision rules and not the probabilities in equation (15), the probabilities remain bounded between zero and one.

A second-order approximation of the policy functions in equation (20) can be found by taking the second derivatives of $\mathbb{F}\left(\mathbf{x}_{t-1}, \varepsilon_t, \chi\right)$. In the end, we have two sets of matrices: $H_{s_t}^{(1)}$ and $G_{s_t}^{(1)}$ characterizing the first-order coefficients; and $H_{s_t}^{(2)}$ and $G_{s_t}^{(2)}$ characterizing the second-order coefficients. Therefore, the approximated policy functions are

$$\mathbf{x}_t \approx \mathbf{x}_{ss} + H_{s_t}^{(1)} S_t + \frac{1}{2} H_{s_t}^{(2)}\left(S_t \otimes S_t\right) \qquad (23)$$

$$\mathbf{y}_t \approx \mathbf{y}_{ss} + G_{s_t}^{(1)} S_t + \frac{1}{2} G_{s_t}^{(2)}\left(S_t \otimes S_t\right) \qquad (24)$$

where $S_t = \left[\ \left(\mathbf{x}_{t-1} - \mathbf{x}_{ss}\right)' \quad \varepsilon_t' \quad 1\ \right]'$.

Our perturbation method produces a stable approximated policy functions, but the method does not guarantee existence or uniqueness of the solution. As we discuss in Appendix B, this limitation is shared with global solution methods of models of occasionally binding constraints that check convergence of the numerical algorithm without guaranteeing

16

existence or uniqueness.[12]

Our solution method is fast, and can readily be scaled to handle larger models. In all, we have 23 equations that characterize the equilibrium, two endogenous and five exogenous state variables, one regime indicator, and six shocks. Our computational approach is similar to that in Fernandez-Villaverde et al. (2015): we use Mathematica to take symbolic derivatives and export these derivatives so that we can use Matlab to solve the model repeatedly for different parameterizations. The model solves in about a second on a standard laptop.[13]

As Appendix C discusses in more detail, the proposed solution method is also accurate. We investigated the accuracy of the proposed solution method in our estimated model, as well as in the smaller calibrated model of Mendoza and Villalvazo (2020) in which we can more easily compare our perturbation method to with global solution methods. In our estimated model, we find Euler equation errors in line with the accuracy of perturbation methods applied to exogenous regime-switching models (Foerster et al., 2016) and standard models without regime-switching (Aruoba et al., 2006). When we compare the endogenous regime switching model solved with our perturbation method with the standard inequality constraint specification of Mendoza and Villalvazo (2020), we find that our model gets close to Mendoza (2010) in terms of moments and bond ergodic distribution, with log-10 absolute Euler equation errors only 2-3 times larger but a solution speed more than 800 time faster.

3.4 Approximation Order and Endogenous Switching and Precautionary Saving

Our endogenous regime-switching framework must be solved at least to the second order to capture the effects of endogenous probabilities on the policy rules, which include precautionary effects that vary with the state of the economy. If we were to use only a first-order approximation, our estimation would not capture precautionary behavior associated with rational expectations about the dependency of the probability of a regime change on the borrowing cushion and the multiplier. The following Proposition states this result formally.

Proposition 1 (**Irrelevance of Endogenous Switching in a First-Order Approximation**)**.** *The first-order approximation to the endogenous regime-switching model is identical*

---

[12]While in some simpler models with collateral constraints it is possible to impose parametric restrictions that rule out multiple equilibria (Schmitt-Grohe and Uribe, 2020; Benigno et al., 2016), in the case of our model, as in Mendoza (2010) and Bianchi and Mendoza (2018), there are no such restrictions and uniqueness must be verified heuristically. We check the mean-squared stability of the first-order approximation paired with the steady state transition matrix $\mathbb{P}_{ss}$ (Farmer et al., 2011; Foerster et al., 2016), and additionally check for explosive simulations.

[13]A code that demonstrates the solution algorithm is available on request from the authors.

to the first-order approximate solution of an exogenous regime-switching model in which the transition probabilities are given by the steady-state value of the time-varying transition matrix.

Proof. *See Appendix B.*

The Proposition illustrates that using a second-order approximation to the solution is necessary to characterize the model properties associated with the endogenous nature of the regime-switching, including particularly precautionary behavior. This result is analogous to the one stating that, in models with only one regime, first-order solutions are invariant to the size of shocks, second-order solutions captures precautionary behavior, and third-order solutions are needed to capture the effects of stochastic volatility (Fernandez-Villaverde et al., 2015). Although, unfortunately, the need to use a second-order approximation along with regime-switching creates additional challenges for estimation purposes. We now turn to our strategy to address them.

4   Estimating the Endogenous Switching Model

We estimate the model with a full information Bayesian procedure. The posterior distribution has no analytical solution and we use Markov-Chain Monte Carlo (MCMC) methods to sample from it. Since the Metroplis-Hastings algorithm that we use for sampling is a standard tool used in the literature, we omit a discussion of this step in our procedure. The details of the construction of the state space representation and the filtering steps for the evaluation of the likelihood are reported in Appendix D.

A key obstacle in sampling from the posterior is the evaluation of the likelihood function. We face three difficulties here relative to linear DSGE models. The first is the non-linearity due to the presence of multiple regimes. The second is the need to approximate to the second-order the model solution that governs the decision rules in each regime. The third is the fact that the transition probabilities are endogenous. Bianchi (2013) develops an algorithm to address the first difficulty. Here we must use an alternative filter to deal with the second-order approximation and endogenous probabilities in a tractable manner. We use the Unscented Kalman Filter (UKF) to compute approximations to the evaluation of the likelihood function using Sigma Points. An alternative would be to use the Particle Filter (Fernandez-Villaverde and Rubio-Ramirez, 2007). However, the Particle Filter is not well-suited to our application, because the regime switching can lead to discarding a large number of simulated particles, lowering accuracy for a given number of particles and greatly increasing the computational cost of obtaining a given level of accuracy. Further, even with

a deterministic filter, the filtering step in estimation is relatively costly at about 10 seconds per likelihood evaluation using Matlab; incorporating the Particle Filter would increase computing time significantly.[14]

The model's posterior distribution is highly non-linear, with many local modes due to the complexity of the model and the features of the data. To deal with this issue, we took the following steps: first, we estimated a version of the model without working capital and the occasionally binding constraint, this step yields an initial estimate of the exogenous processes and the non-financial parameters; second, conditional on these initial estimates, we performed a grid search over the remaining parameters (κ, ϕ, γ_0, and γ_1) to find high posterior regions; third, from the high posterior regions of the grid search, we used a mode-finding routine to identify the posterior mode, which forms the basis for our empirical results; lastly, we sampled $500,000$ times from the posterior with a random-walk Metropolis-Hastings algorithm to explore the parameter space around the mode and characterize credible sets for the parameter estimates.[15]

4.1 Observables, Data, and Measurement Errors

The model is estimated with quarterly data for GDP growth (gross output less intermediate input payments), consumption growth, investment growth, and intermediate import price growth, as well as the current account-to-output ratio, and a measure of the country real interest rate. GDP, consumption, and investment are in quarterly, demeaned log differences.[16]

As there are six shocks with six observables, we do not need measurement errors. However, measurement errors in the observation equation improves performance of the non-linear filter and accounts for any actual measurement error in the data. To limit their impact on the inference, we limit their variance to 5% of the variance of the observable variables. This means that our model will fit the data relatively closely on average; thus, how it performs across cycles and crises and whether it relies on large shocks to fit the data will be important in assessing model performance.

---

[14]See Binning and Maih (2015) for a comparison between the Sigma Point filter and the Particle Filter in a regime-switching context, which includes degeneracy issues.

[15]For the last MCMC step, we adjusted the scale of the proposal density until we achieved an acceptance rate of 0.25. The entire MCMC algorithm takes 58 days to complete.

[16]See Appendix F for details on variable definitions and data sources. The country interest rate is constructed following Uribe and Yue (2006) and it is the US 3-Month Treasury Bill minus ex post US CPI inflation rate plus Mexico's EMBI Spread.

Table 1: Calibrated Parameters

Parameter	Description	Value
β	Discount Factor	0.9798
ρ	Risk Aversion	2.0000
ω	Labor Supply	1.8460
η	Capital Share	0.3053
α	Labor Share	0.5927
δ	Depreciation Rate	0.0228
P^*	Mean Import Price	1.0280
E^*	Mean Expenditure	0.2002
ψ_r	Interest Rate Debt Elasticity	0.0010
$\bar{B}$	Neutral Debt Level	-6.1170

4.2 Calibrated Parameters and Prior Distributions

Our objective is to estimate critical parameters governing the model's dynamics in both the binding and non-binding regime, as well as the parameters that govern the transitions between regimes on which we do not have any prior information. To make inference on the parameters of interest while using relatively diffuse priors, we calibrate a subset of parameters on which we have reliable prior information. We now discuss our calibrated parameters, and then our use of priors in estimation.

Table 1 lists the parameters that we calibrate.[17] We set these parameters largely following Mendoza (2010), who calibrated them based upon stylized facts from Mexico's National Accounts, but adapted to our model specification and the quarterly data frequency. One parameter that does not come from Mendoza (2010) is β, which we set to match the capital-to-output ratio. Another important parameter that we calibrate is ψ_r, which is estimated in Garcia-Cicco et al. (2010). We set it to a very small value for the sole purpose of eliminating the dependency of the steady state on initial conditions, while not allowing it to affect the model dynamics (see Schmitt-Grohe and Uribe, 2003). Setting ψ_r to a very small value allows us to evaluate the model's ability to match the behavior of the trade balance and the other key stylized facts of the data without introducing an additional financial friction in the form of a quantitatively important endogenous component of the market interest rate in equations (5)-(6).

Table 2 below summarizes our assumptions on the prior distributions. We set two types of priors on the parameters to be estimated. The first type of prior is set directly on the parameters. They impose sign restrictions and put lower prior probability on parameter values that generate implausible moments in model simulations. The second type of prior

---

[17]See Appendix E for more details on the calibration and the targeted data moments.

Table 2: Estimated Parameters

Par.	Description	Prior	Posterior

Notes: Estimated parameters, with prior distribution and posterior moments. Priors are Normal, Uniform, Beta, or Inverse Gamma; prior distributions show mean and variance, except for uniform where lower and upper bounds are shown. Posterior distribution shows mode, along with 5-th, 50-th, and 95-th percentiles from MCMC posterior draws.

is on a model-implied object: the steady state transition probability of switching from the binding to to the non-binding regime, given by the steady state value of equation (13), $\Pr(s_{t+1} = 1 | s_t = 0, B_{ss}^*)$. This prior is a Beta distribution with mean 0.25 and variance of 0.25. It puts lower probability mass on combinations of parameters that either generate extremely infrequent transitions to the binding regime, or that imply the economy exits the binding regime almost immediately.[18]

5 Empirical Results

Our empirical findings comprise four sets of results. First, we present the estimated parameters characterizing the tightness of the working capital and borrowing constraints and the endogenous transition probabilities. Second, we examine the estimated model's fit to the data. Third, we examine the model's performance from a business cycle perspective, com-

---

[18]Priors on model-implied objects have been used by, for example, Otrok (2001) and Del Negro and Schorfheide (2008).

paring moments in the model and the data and assessing the relative importance of different shocks. Our fourth set of results focuses on financial crises. We report and discuss the first three sets of results in this section, and present the fourth set in Section 6.

5.1   Estimated Parameters

The first set of results focuses on the estimated parameters. Table 2 reports the mode, the median, the 5th, and the 95th percentile of the posterior distribution of the estimated structural parameters of interest. The estimated mean interest rate, slightly below 1.75% per quarter, is close to the value estimated by Mendoza (2010). The posterior coverage interval for this variable is fairly diffuse, indicating some uncertainty in its true value. The remaining parameters have tightly estimated posteriors, so we will focus the discussion on posterior modes.

Importantly, the model provides precise estimates of the investment adjustment cost, working capital, and leverage parameters, and the parameters of the logistic function. These parameters cannot be easily measured directly from stylized facts of the data—unlike, for example, capital or labor shares—but are nonetheless critical for explaining the behavior of the economy and the amplification of shocks.

The estimated investment adjustment cost parameter (ι) that controls investment volatility is 12.7. This parameter is model dependent and its magnitude has no interpretation outside of a particular model; for example, Mendoza (2010) calibrated this parameter to 2.75 at an annual frequency. The estimate for the working capital constraint parameter indicates that 71% of the wage and intermediate good bill needs to be paid in advance with borrowed funds. This estimate is substantially higher than the 25.79% value set by Mendoza (2010), but much lower than the 100% used by Neumeyer and Perri (2005) or the 125% used by Uribe and Yue (2006). The estimate is the closest to the 60% estimated by Ates and Saffie (2016), who use interest payments and production costs from Chilean microeconomic data. The estimated value of the leverage parameter in the borrowing constraint (κ) is 0.17, indicating less than a fifth of the value of capital serves as collateral. The estimate is slightly tighter than the benchmark value of 0.20 chosen by Mendoza (2010), and on the low end of the 0.15 to 0.30 range of alternative values considered in that calibration.

The posterior modes of the logistic parameters in equations (13) and (14) are 13.6 and 17.8, respectively, estimated in a tight range relative to the very loose prior. These estimates are significantly different from zero, thus suggesting that the data reject a model specification in which the transition probabilities are exogenous, which is in principle allowed for under the prior distribution.

Figure 2: Logistic Functions and Distributions of Their Arguments

(a) Borrowing Cushion and Transition Probability in Non-Binding Regime
### (b) Multiplier and Transition Probability in Binding Regime
Note: The top panel shows the model-implied distribution of the borrowing cushion B^* in the non-binding regime, and the logistic transition function to the binding regime as in equation (13) implied by our estimates. The bottom panel shows the model-implied distribution of the multiplier λ in the binding regime, and the transition function to the non-binding regime as in equation (14) implied by our estimates.

Figure 2 plots the implied probabilities from equation (13) and (14), evaluated at the posterior mode value of γ_0 and γ_1, together with the estimated ergodic distributions of their arguments, the borrowing cushion, B^* and the the constraint multiplier, λ. The figure shows that the ergodic distribution of the borrowing cushion is centered on a positive value, as the economy spends most of its time in the non-binding regime, above the borrowing limit. As the borrowing cushion falls, the probability of switching to the binding regime increases, and gradually reaches 1 for small negative values, with very little probability mass on large negative realizations of the borrowing cushion.

On the other hand, once the economy is in the binding regime, the ergodic distribution of the multiplier is centered on small negative values, with more probability mass on the right tail than the left tail. As λ approaches 0 from the positive side of the support, the probability of switching to the non-binding regime increases and quickly reaches 1, with a mode on a small negative value. Nonetheless, there is a significant probability mass for larger

negative values. As we explained earlier, negative values of λ reflect instances in which had the economy been in the non-binding regime, the borrowing cushion would be positive, but a switch to the non-binding regime at has not been drawn yet.[19]
5.2 Model Fit

Our second set of results provides evidence on how the estimated model fits the observable variables. The model fit is summarized by Figure 3, which plots observable variables used in the estimation together with the fitted values. The Figure also includes the peaks of the model-identifed crises (red bars), which we define and discuss in more detail in Section 6 and are the trough quarters of the model-identified crisis episodes. The fitted series tracks the actual data very closely. Importantly, the model estimates track the data consistently throughout the sample, during both regular business cycle and crisis periods. For example, around the 1995 "Tequila Crisis," the data show large drops and rebounds in output, consumption, and investment growth, and a very sharp reversal in the current account to output ratio. If, by contrast, one were to observe a loss of fit during crisis episodes, it would suggest that our estimated model finds it difficult to match the data dynamics during these episodes of critical interest in the empirical analysis.

Figure 4 plots the estimated model implied shocks in standard deviation units, together with a two-standard deviations band. As we can see, the estimated model fits the data quite well without relying on large or skewed shocks, including particularly during crisis times. Instead, it explains crisis dynamics using the model's internal propagation mechanisms that amplify the effects of normally sized shocks. Shocks slightly outside the two-standard divisions band are estimated right before the 1982 debt crisis, possibly do to the limited number of observations before the peak of that crisis episode. TFP, expenditure, and preference shocks, however, are all well within the band during the that event. Moreover, the few shock realizations slightly outside the two-standard deviation band are both positive and negative. The largest shocks occur for the import price shock, which is implied directly from the observable data on import prices. The shock processes thus provide evidence that the skewness that is evident in the raw data is picked up by the regime switching and the propagation mechanism of the model rather than the estimated shocks.

---

[19]Sufficiently negative values of λ, approximately below -0.2, produce a nearly deterministic switch back to the binding regime. The ergodic distribution of λ in the binding regime (Figure 2b) implies that the probability of exiting that regime exceeds 99% about 1/4-th of the time.

Figure 4: Model Estimated Shocks

Notes: The table compares second moments of the data, relative to the same moments simulated from the model.

5.3 The Anatomy of Business Cycles

In our third set of results, we discuss second moments to characterize the estimated model dynamics and variance decompositions to identify key drivers of the business cycle.[20] All statistics reported are unconditional, rather than conditional on a particular regime.

Table 3 compares data and simulated model second moments, reporting results for three variables used in estimation (output, consumption, investment and the country interest rate), and one critical variable, the trade balance ratio, not used in estimation. The model matches the business cycle moments quite well, fitting both the relative volatilities and the correlations with output. The volatility ranking is correct, with consumption significantly more volatile than output, which is a robust stylized fact of emerging market business cycles. The model underestimates the relative volatility or the trade balance ratio and, particularly, the country interest rate. The model implied comovements of all variables match the data counterparts remarkably well, again with the exception of the country interest rate, whose correlation is not estimated precisely in the model. The trade balance, in particular, which is not an observable variable used in estimation, is counter-cyclical as in the data, with a model-implied autocorrelation coefficient (not reported) well below one.

Table 4 reports variance decompositions. The table illustrates that all shocks play a quantitatively sizable role in the model, even though different shocks matter more for different variables. Output and consumption are mostly driven by productivity, preference, expenditure, and terms of trade shocks, respectively. Investment is significantly affected by expenditure, preference, productivity, terms of trade, and persistent interest rate shocks. Expenditure and persistent interest rate shocks are the most important drivers of the trade

---

[20]All business cycle and crisis statistics in this and the following section relying on simulated data. For these simulations, based on the posterior mode estimates, we generate 10,000 samples of 144 quarters length (the same as our data sample), after a burn-in period of 1,000 quarters. We then compute and report median values across these 10,000 runs. We use a pruning method (Andreasen et al., 2018) to avoid explosive simulation paths.

Table 4: Estimated Unconditional Variance Decomposition

Variables / Shocks	TFP	Expend.	Import Prices	Pref.	Temp. Int. Rate	Pers. Int. Rate
Output	33.2	17.2	15.7	25.4	2.5	6.0
Consumption	30.3	23.4	14.3	20.6	3.8	7.6
Investment	19.2	29.8	10.3	25.6	4.6	10.5
Trade Bal/Output	9.5	35.2	8.8	17.2	9.2	20.1
Interest Rate	0.0	0.0	0.0	0.0	21.1	78.9
Borrowing Cush.	10.6	32.3	9.9	21.3	9.9	16.0
Debt/Output	15.2	25.5	7.6	40.9	1.4	9.5
Multiplier	9.5	40.5	9.5	18.1	9.6	12.8

Note: The variance decomposition is normalized to sums to 100 by row, but estimates may not add up to 100 exactly due to rounding. The decomposition is computed by setting each shock to zero to compute its marginal impact on each variable. The computation abstracts from non-linear interactions across shocks for ease of comparison with linear models.

balance, while the country interest rate is clearly driven by persistent interest rate shocks, and to a lesser extent by the temporary component of the cost of borrowing. Demand shocks (expenditure and preference) and interest rate shocks (permanent and temporary components) play a more important role than productivity and terms of trade shocks for financial variables and the multiplier.

While the magnitude of these variance shares are not directly comparable with those estimated by Garcia-Cicco et al. (2010), Fernandez and Gulan (2015), and Schmitt-Grohe and Uribe (2018), they suggest that both real and financial shocks matter for Mexico business cycles. In particular, we find a lower share for productivity and interest rate shocks than Fernandez and Gulan (2015), although we also consider terms of trade and demand shocks. We also find a share of variance explained by terms of trade shocks that is very close to the structural vector autoregression model estimated by Schmitt-Grohe and Uribe (2018). The estimated share of the variances explained by interest rates shocks is in general smaller than those estimated by Garcia-Cicco et al. (2010), who use a different specification of the financial friction with a more sizable debt elastic country premium, without amplification mechanism from the financial accelerator (Fernandez and Gulan, 2015), or the working capital (Neumeyer and Perri, 2005; Mendoza, 2010; Fernandez and Gulan, 2015; Ates and Saffie, 2016).

6 The Anatomy of Financial Crises

In this Section, we turn to our fourth and main set of empirical results, which examine the model's ability to describe and interpret financial crises. We start by defining financial crises episodes in a model consistent manner and discuss the inference that we can draw based on the estimated model. Next, we investigate the drivers of the three historical episodes of sudden stop that the estimated model identifies in the data: the Debt Crisis of the 1980s, the 1995 'Tequila' Crisis, and the spillover of the Global Financial Crisis (GFC) in 2008-2009. Then we study the model-implied duration and frequency of these episodes in simulations. Finally, we illustrate the model-based dynamics of sudden stop episodes of duration comparable to those realized over Mexico's recent history.

6.1 Model-based Definition and Estimates of Sudden Stop Episodes

The estimated model allows us to make inference on whether the economy is in the binding regime, and hence identify periods of sudden stop crisis in a model-consistent manner. In the model, the regime is known by the household-firm, but the estimation procedure does not observe the regime, and it must be inferred based on the information in the data. The estimation results, therefore, can provide a time-varying estimate of the (smoothed, i.e. based upon the full sample) probability of being in each regime. Figure 5 plots this estimated probability (solid black line).[21]

Using the information in Figure 5, we can provide a model-consistent definition of a *crisis quarter* as one in which the economy is in the binding regime with probability higher than at least a 90% probability.[22] A *crisis episode* can then be defined as a sequence of such periods. For reference, we also identify the peaks of crisis episodes (red bars) as periods in which (i) the smoothed estimate of the probability of being in the binding regime is at least 90%, (ii) the model estimate of output growth (Figure 3, Panel a) is negative by more than one standard deviation, and (iii) the model estimate of the current account ratio (Figure 3, Panel e) increases by more than one standard deviation.[23]

Figure 5 shows that the model identifies three crisis episodes (start and end quarters

---

[21]The estimated model also provides an estimate of the time-varying transition probability based upon equations (13-14). These are reported in Appendix G and confirm that an exogenous regime switching specification would be rejected by the data.

[22]This threshold is intuitive but somewhat arbitrary. The duration of the identified sudden stop episode identified, however, is robust to using a wider range of values.

[23]As Figure 3 shows, the identified peak crises periods corresponds to the trough in output, consumption, investment growth in the data, and the peaks in the current account adjustment and interest rate increases. The definition of these crisis peaks is in line with the one employed in the quantitative literature modeling sudden stops with occasionally binding constraints (for example, Mendoza, 2010; Benigno et al., 2013).

Figure 5: Mexico's Model-identified Crisis Episodes

(a) Probability of Binding Regime and Reinhart-Rogoff Tally Index

(b) Probability of Binding and OECD Recessions
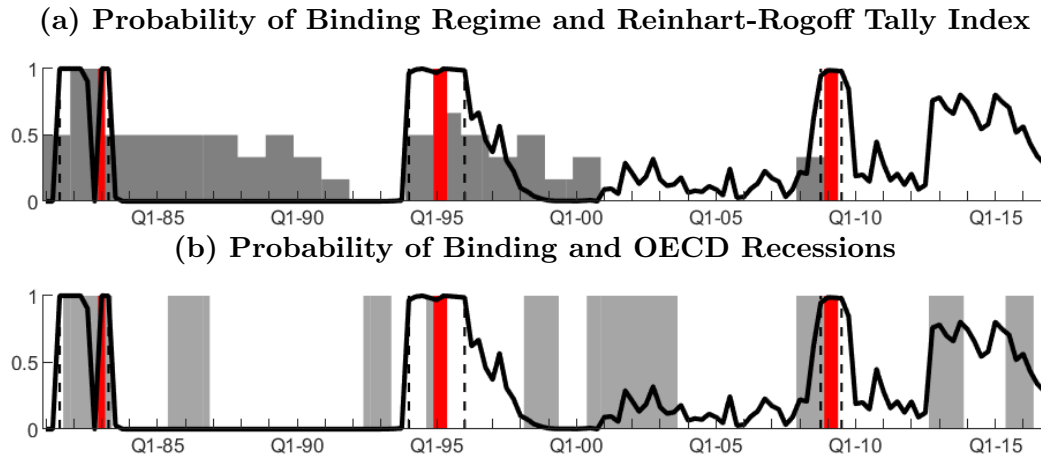

Notes: Black line shows the model implied smoothed probability of being in the binding regime. The dark gray regions in panel (a) indicates Reinhart and Rogoff (2009) tally index of financial crisis, normalized so that it takes values between 0 (no crisis) and 6 (most severe). Light gray regions in panel (b) indicate OECD recession dates for Mexico. Red bars indicate model-identified crisis peaks, vertical blacked dash lines indicate the beginning and the end of the estimated crisis episodes; see text for details.

marked by vertical dashed lines). The first is the Debt Crisis, which the model identifies as occurring from 1981:Q3-1983:Q2, with an associated peak in 1983:Q1. The second episode is the Tequila Crisis, which the model identifies in 1994:Q1-1996:Q1, with its peak in 1995:Q1-Q2. Last, the model identifies the GFC as producing a crisis in Mexico during 2008:Q4-2009:Q3, with a peak in 2009:Q1-Q2. Figure 5 also reports a purely empirical definition of financial crisis (dark grey shaded areas in Panel a) and the OECD dating of the business cycle of Mexico (light grey shaded areas in Panel b). The empirical notion of financial crisis reported is a normalized version of the *crisis tally* index of Reinhart and Rogoff (2009) (RR).[24] Figure 5 illustrates that our estimated probability of being in a binding regime, which is our model-consistent definition of crisis, aligns quite well with the RR tally index. The crisis episodes that our model identifies track the RR tally index remarkably well in the case of the Tequila and GFC episodes, and are much more persistent than the crisis peaks typically identified in the sudden stop literature. This result is consistent with the idea that our stochastic specification of the borrowing constraint better characterizes how lending limits applies to households and firms in the data. Our model's crisis signal is less persistent than the tally index in the aftermath of the Debt crisis. This is to be expected, however,

---

[24]The RR tally index ranges from 0 to 6, depending on whether a country-year observation is deemed to be in one or more of the following 6 varieties of crisis, assigning the value of one if a variety is present: Currency, Inflation, Stock Market, Sovereign Domestic or External Debt, and Banking Crisis. See Chapter 1 of Reinhart and Rogoff (2009) for more details. We follow their methodology to extend the index to cover our full sample. In Figure 5, the index is normalized to range between 0 and 1.

as our model economy is not designed to capture debt overhang or financial intermediation disruptions that drive the classification of RR between 1983 and 1989 and in the mid-1990s.

Importantly, our model estimates of these sudden stop episodes do not mistake ordinary recessions, not associated with spikes in the tally index, for crisis periods. Mexico OECD recessions are illustrated by the light dark shaded areas in Figure 5 Panel (b). The estimated probability of a binding regime is close to 0 during the OECD recessions before the Tequila crisis, during the US recession in 2001, and the Argentine crisis in 2000-2001. The estimated probability of a binding regime also does not register stress during the 1998 Russian default and US Long-Term Capital Management debacle that affected only the currency and stock market, without triggering a sudden stop in Mexico.

Overall, Figure 5 shows that our model provides an accurate signal of when the economy is likely to have experienced a crisis, without mistaking regular recessions or large currency and stock market movements for financial crisis episodes. In the rest of this section, we study the model-implied properties of these crises episodes—first examining which shocks drove the three identified episodes in Mexico's history, and then studying the frequency, duration and dynamics of model-implied episodes based on simulations.

6.2 Drivers of Mexico's Sudden Stop Episodes

As we saw earlier, our estimated model fits Mexican data well (Figure 3), including during the crisis episodes identified in Figure 5. We now examine the sudden stop episodes identified, evaluating the relative importance of different shocks driving the economy before, during and after the Debt Crisis of the early 1980s, the Tequila Crisis of 1994-1995, and the spillover on Mexico from the GFC that originated in the United States in 2008-09. This exercise is possible because we have a likelihood-based estimation of the model that produces sequences of shocks, allowing for the construction of such historical counterfactuals.

The multiple sources of non-linearity in the model, the endogenous regime-switching plus the second-order approximation, pose a challenge for computing historical counterfactuals. The task is complicated by the fact that shocks not only have non-linear effects on the endogenous variables, but also on the realization of the regimes in subsequent periods. Therefore, rather than decomposing the change in individual endogenous variables, we compute a broader summary measure, namely the importance of each shock in terms of model fit and hence likelihood. Specifically, we counterfactually recalculate the model likelihood, evaluated at the posterior mode, turning one shock off at the time, while leaving all other shocks at their estimated values, over a particular sub-sample period and repeat the calculation for all six shocks. The details of this calculation are in Appendix G.

Table 5: Estimated Relative Importance of Shocks in Mexico's Crises

Time Period	TFP	Exp.	Imp. Prices	Pref	Trans Int Rt.	Persist Int Rt.
1983 Debt Crisis						
Two Quarters Prior (81:Q1-Q2)	0.4	0.4	**0.7**	-3.2	**0.9**	**0.8**
During Crisis (81:Q3-83:Q2)	**0.4**	**5.3**	-2.0	-2.8	0.0	-0.8
Two-years After (83:Q3-85:Q2)	**0.8**	**1.0**	-0.6	0.2	-0.7	-0.7
1995 Tequila Crisis						
Two-years Prior (92:Q1-93:Q4)	-0.1	-1.0	**0.4**	**0.7**	0.1	-0.1
During Crisis (94:Q1-96:Q1).	-2.2	-0.7	**0.5**	**1.3**	0.2	**0.9**
Two-years After (96:Q2-98:Q1)	-0.1	-0.2	0.2	**1.1**	**-0.6**	**-0.4**
2009 Global Fin. Crisis						
Two-years Prior (06:Q4-08:Q3)	-0.7	**2.1**	-0.7	-0.2	-0.7	**0.2**
During Crisis (08:Q4-09:Q3).	**0.2**	-1.2	**0.3**	**0.5**	**0.2**	0.0
Two-years After (09:Q4-11:Q3)	-0.4	-1.1	**0.4**	**0.8**	**0.1**	**0.1**

Note: The table reports a likelihood-based measure of the importance of each shock relative to all shocks in the model, during different sub-sample periods, compared to their average relative importance over the full sample, in percentage point differences. For example, a value of +1 indicates that the shock has an average 1 percentage point greater relative importance in the sub sample relative to its average relative importance over the full sample, and indicates a change in the log-likelihood of about 5 points. See Appendix G for details. Values in bold font highlight the most important shocks in each period according to this metric. The prior period before the 1983 Debt Crisis is limited by the data sample length.

Table 5 reports this likelihood-based measure of shock relative importance. As Appendix G explains, the measure is the average importance of a shock in a given period relative to all shocks in the model, relative to their average importance over the full sample. "Importance" is assessed in terms of likelihood point loss when the shock considered is set to zero. For each of the three crisis episodes, we consider the crisis episodes themselves, as well as two years before and two years after the episode. Positive (negative) numbers denote relatively more (less) important shocks in a given sub period. For example, a value of +1 means that the shock is relatively more important in that period relative to its average importance over the full sample. A one percentage point change implies a change in the log-likelihood by about 5 log-points, on average. By definition, the percentages in Table 5 sum to zero by row.

As the variance decomposition in Table 4 showed, each shock plays some role in explaining fluctuations different crises or different phases of a particular crisis, highlighted by the fact that no individual shock has a disproportionate importance in any particular period. Consider first the Debt Crisis. Since this episode starts right at the beginning of the sample

period, we can only look at the two quarters before its start. The counterfactual analysis suggests that in the immediate run up, the most important shocks were imported intermediate input prices and both temporary and persistent interest rate shocks, consistent with the drop in oil prices starting in 1981 and the Volcker disinflation in the United States. The crisis episode itself and its aftermath appears driven by the expenditure and technology shocks, possibly reflecting the import and fiscal contraction typically associated with a sudden stop and its aftermath, and the loss of efficiency associated with sudden adjustment of expenditure plans due to tighter financial frictions.

Next, consider the Tequila Crisis. The estimated model identified a peak crisis lasting two quarters in 1995:Q1-Q2. According to our counterfactual results, in the run up to this crisis episode, the most important drivers were the preference shock and imported input price shocks. The importance of these two shocks increases during the crisis episode, even though the shock to the persistent component of the interest rate also becomes more important. The likelihood weight of preference and interest rate shocks declines after the crisis, while the weight in the likelihood of the technology shocks increases during this phase in relative terms. In the post-crisis period, the preference shock continues to play a role, while the importance of shocks to both components of the interest rate decline markedly. Overall, therefore, the main driver is the preference shock.

Lastly, consider the GFC episode. The counterfactual likelihood analysis suggests that, before the crisis, expenditure and to a lesser extent a shock to the persistent component of the interest rate were the most important drivers. This is consistent with the lax international financial conditions, strong external demand, and possibly loose domestic fiscal domestic policy prevailing before the GFC. However, all other shocks become more important during the crisis episode itself, consistent with the collapse of the oil price in during the fall of 2008 and spike in emerging market spreads. In the aftermath of the episode, the likelihood weight of the import price shock and temporary interest rate shock diminishes, while that of the preference and persistent interest shocks increases, confirming the importance of international financial conditions during this episode.

6.3   Duration and Frequency of Simulated Crisis Episodes

We now look at the duration and frequency of crisis episodes simulated from the estimated model, shown in Figure 6.[25] The estimated model generates substantial heterogeneity in

---

[25]We simulate 10,000 samples of 144 quarters length, as in our data series. Note however that in these simulations the household-firm always knows in which regime the economy is. Therefore, there is no sampling uncertainty about being in the binding regime, in contrast to the econometrician's perspective reported in Figure 5.

Figure 6: Model-simulated Crisis Duration and Frequency

(a) Crisis Episodes of at least Four Consecutive Quarters
**(b) Frequency of Crisis Episodes of Any Duration per Sample**

(c) Number of Quarters in Binding Regime per Sample

Note: Histograms of the model-implied (a) conditional crisis duration, (b) frequency of distinct episodes of any duration in 144 quarter-long samples, and (c) number of quarters in the binding regime in 144 quarter-long samples.

crisis duration and frequency. Panel (a) is an histogram of simulated crisis episodes. Given that the shortest of the three crisis episode identified in estimation (the GFC) lasted four quarters, here we consider episodes in which the economy is in the binding regime for *at least* four consecutive quarters. The average conditional duration is 4.95 consecutive quarters in the binding regime. Some of the simulated episodes last up to 22 consecutive quarters though, but they are rare events, as they make up less than a half-percent of all simulated crisis episodes.

Panel (b) counts of crisis episodes of at least four quarters *per sample period* of 144 quarters length. The most common occurrence is four distinct crisis episodes that is close to our estimation results, which show three distinct events in Mexico's history. However, there is significant heterogeneity, as some samples have no episodes at all, while others experience

34

as many as eight-ten crisis events of short duration per sample.

Building on Panels (a) and (b), Panel (c) counts the total number of quarters in crisis episodes out of 144. The model-implied mean is 21.5 quarters, consistent with our estimates in Figure 5 that suggested that Mexico spent 21 quarters in crisis on average over the sample period. The standard deviation however is about 10 quarters, with a long right-tail and a maximum of 62 quarters in the binding regime.[26]

6.4 Dynamics of Model-simulated Crisis Episodes

We finally turn to model-simulated crisis dynamics shown in Figure 7. As the more severe historical episodes of sudden stop identified in Figure 5 in the early 1980s and mid-1990s lasted about 8 quarters, we report results for episodes of such duration. The Figure plots the model dynamics during crisis episodes of eight consecutive quarters (starting at $t = 0$ and ending at $t = 7$, vertical dashed lines), as well as 5 years (20 quarters) before the beginning of the episode and 10 years (40 quarters) after the end of the event. Variables are in log-levels, normalized to zero at the beginning of the pre-crisis period that is time $t = -20$.
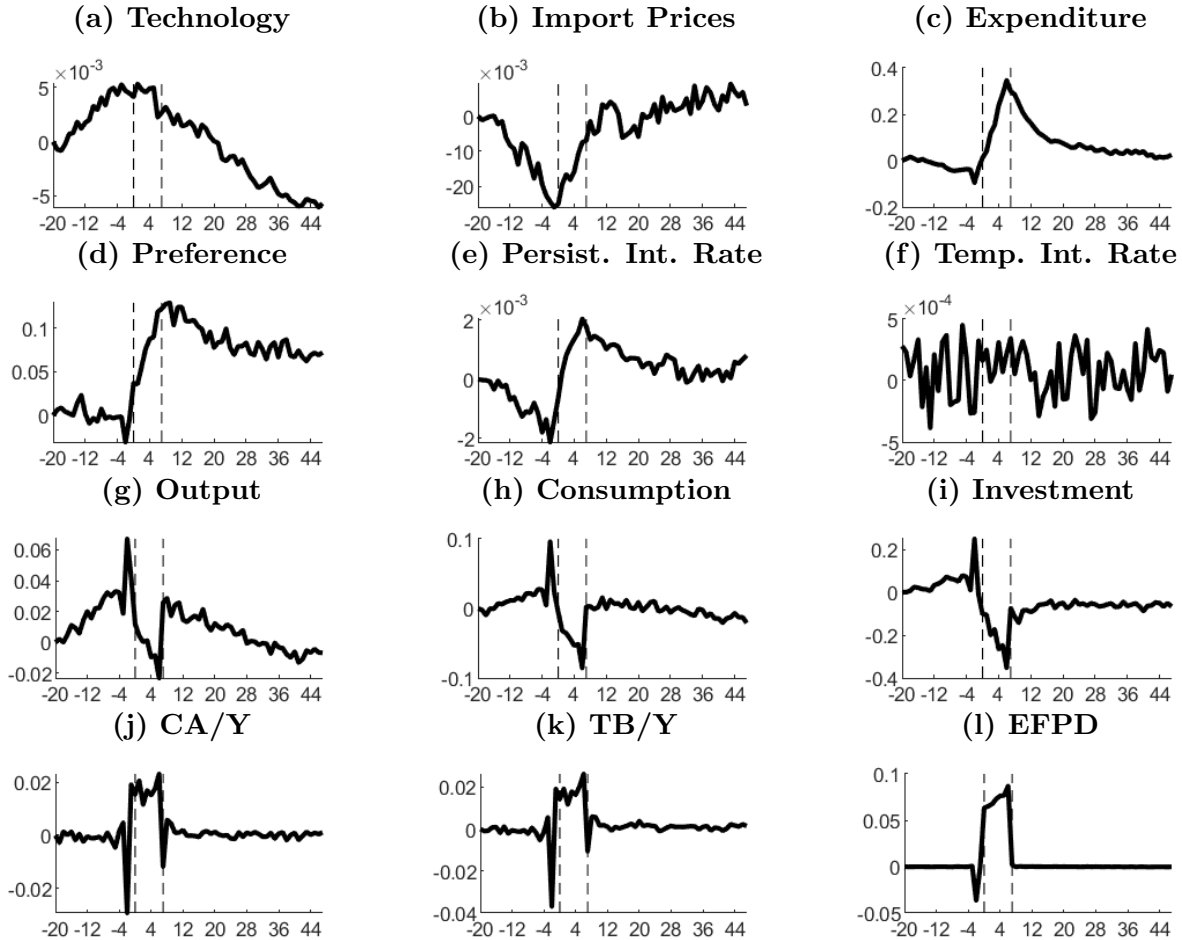

Figure 7 shows the distinctive combinations of shocks that drive the economy before, during and after the crisis episode. Crisis episodes are preceded by a long-lasting "boom" phase, driven by improving technology and a favorable international environment, with improving terms of trade and a decline in the persistent component of the market interest rate. These three forces drive the expansion gradually, with increasing output, consumption and investment, in a manner consistent with empirical characterizations of the boom phases of financial crises (Boissay et al., 2016).

The economy enters the crisis episode at $t = 0$, after a final acceleration, driven by an increase in expenditures and a fall in patience. The crisis episode is precipitated by a small negative technology shock and a sudden reversal of the favorable external environment that drove the boom phase. During the crisis episode, imported intermediate inputs and the cost of funding increase; the effective cost of borrowing spikes, driven by the external finance premium on debt (EFPD). Technology stagnates and patience increases sharply during the crisis. The constraint on borrowing limits consumption smoothing and curtail the supply side of the economy through the working capital constraint, causing output, consumption and investment to drop sharply. The output drop from peak to through is eight percentage points, in line with what observed during the Tequila crisis. The trade-balance-to-output ratio

---

[26]Also, when we compute frequency statistics for simulated crisis peaks—the analogous to the red bars in Figure 5—we find a mean frequency of about 2.4% of the quarters in the binding regime, very close to the typical estimates in the empirical literature on sudden stops (Calvo et al., 2006), but with significant heterogeneity (results not reported).

(j) CA/Y

(k) TB/Y

(l) EFPD

Notes: The figure plot model-simulated dynamics during crisis episodes of eight quarters, five years (20 quarters) before the crisis, and 10 years after the crisis (40 quarters). The economy is in the binding regime from period $t = 0$ to period $t = 7$ (vertical dashed lines). The plotted dynamics in all panels are medians across all crisis episodes identified, in log-levels, setting $t - 20 = 0$.

suddenly reverts, improving persistently during the crisis phase, after a sharp deterioration right before the beginning of the event, by about six percentage points as a share of output from trough to peak. In line with these dynamics, the autonomous component of expenditure continues to increase during the crisis period, which can be interpreted in terms of the import compression typically associated with sudden stops.

The economy rebounds quickly from these crisis episodes, but only partially, recovering only half of the ground lost during the crisis or about 4 percentage points. After the initial rebound, a combination of persistently adverse external and internal circumstances coalesces to produce a protracted output decline, as we can see in the Mexican data after the Debt crisis, and also in line with empirical evidence on the long-term consequences of financial crises in other emerging markets in (Cerra and Saxena, 2008). The cost of borrowing and

intermediate imported inputs remain elevated for an extended period of time after the crisis episode. The productivity decline is very long lasting, reaching a significantly lower level compared to before the beginning of the boom phase of the crisis. Expenditure and patience also do not recover to pre-crisis levels ten years after the end of the episode. During the post-crisis period, investment and to a lesser extent consumption stagnate below their pre-crisis levels (Benigno and Fornaro, 2018). As a result, the trade balance remains above its the pre-crisis level long after the crisis has ended.

7 Conclusions

In this paper we propose a new approach to specifying and solving DSGE models with occasionally binding frictions that is suitable for structural estimation. This permits estimating such models using full information methods, obtaining estimates of critical model parameters and conducting likelihood-based inference and counterfactual experiments. The critical step in our approach is to specify the occasionally binding nature of the friction stochastically, so that the formulation can be mapped into an endogenous regime-switching model.

We apply this new approach to a workhorse medium-scale model of financial crises, the so-called sudden stops in capital flows, and estimate it with Bayesian methods on quarterly data for Mexico since 1981. We find that the estimated model fits Mexico's business cycle and crisis episodes well, critical parameter estimates differ from values previously used in the literature, and that different shocks matter for different variables and phases of financial crisis dynamics. In particular, we show that the model can generate heterogeneous crisis episodes of varying duration, frequency, and intensity. Specific combinations of shocks typically drive the economy before, during, and after crisis episodes. Finally, we document that our estimated model identifies sudden stops that are longer lasting and more in line with narratives of Mexico's history of financial crises than those typically simulated with traditional inequality specifications of the collateral constraint.

We regard the estimation of larger models—including those with nominal or labor market frictions, those with permanent and temporary productivity shocks over longer sample periods, those with financial intermediation or equilibrium default, and those that embed endogenous probability of infection—as important areas of future research. Such models would be useful lenses to understand episodes like the Great Depression, the Global Financial Crisis, and the COVID-19 Crisis. Another important area of future research is to study contracting environments in which the economy switches endogenously but stochastically between lending regimes, consistent with growing microeconomic evidence of covenant contract violations and financing cut off periods of varying duration as we assumed.

Appendix A Model and Equilibrium Definition

This Appendix derives the model's equilibrium conditions and defines a competitive equilibrium.

A.1 Derivation of Equilibrium Conditions

The household-firm maximizes the utility function

$$U \equiv \mathbb{E}_0 \sum_{t=0}^{\infty} \left\{ d_t \beta^t \frac{1}{1-\rho} \left(C_t - \frac{H_t^\omega}{\omega} \right)^{1-\rho} \right\}, \tag{A.1}$$

subject to

$$C_t + I_t = A_t K_{t-1}^\eta H_t^\alpha V_t^{1-\alpha-\eta} - P_t V_t - \phi r_t \left(W_t H_t + P_t V_t \right) - E_t - \frac{1}{(1+r_t)} B_t + B_{t-1} \tag{A.2}$$

where gross investment follows

$$I_t = \delta K_{t-1} + (K_t - K_{t-1}) \left(1 + \frac{\iota}{2} \left(\frac{K_t - K_{t-1}}{K_{t-1}} \right) \right). \tag{A.3}$$

In the binding regime, the collateral constraint is given by

$$\frac{1}{(1+r_t)} B_t - \phi \left(1 + r_t \right) \left(W_t H_t + P_t V_t \right) = -\kappa q_t K_t \tag{A.4}$$

with the corresponding multiplier denoted λ_t. In the non-binding regime, the collateral constraint equation drops out, and the multipler is $\lambda_t = 0$. The first-order conditions of this problem are the following:

$$d_t \left(C_t - \frac{H_t^\omega}{\omega} \right)^{-\rho} = \mu_t; \tag{A.5}$$

$$(1 - \alpha - \eta) A_t K_{t-1}^\eta H_t^\alpha V_t^{-\alpha-\eta} = P_t \left(1 + \phi r_t + \frac{\lambda_t}{\mu_t} \phi \left(1 + r_t \right) \right); \tag{A.6}$$

$$\alpha A_t K_{t-1}^\eta H_t^{\alpha-1} V_t^{1-\alpha-\eta} = \phi W_t \left(r_t + \frac{\lambda_t}{\mu_t} \left(1 + r_t \right) \right) + H_t^{\omega-1}; \tag{A.7}$$

43

$$\mu_t = \lambda_t + \beta \left(1 + r_t\right) \mathbb{E}_t \mu_{t+1}; \tag{A.8}$$

$$\mathbb{E}_t \mu_{t+1} \beta \left(\begin{array}{l} 1 - \delta + \left(\frac{\iota}{2} \left(\frac{K_{t+1}}{K_t} \right)^2 - \frac{\iota}{2} \right) \\ + \eta A_{t+1} K_t^{\eta-1} H_{t+1}^\alpha V_{t+1}^{1-\eta-\alpha}; \end{array} \right) = \mu_t \left(1 - \iota + \iota \left(\frac{K_t}{K_{t-1}} \right) \right) - \lambda_t \kappa q_t. \tag{A.9}$$

Market prices for capital and labor satisfy the following two conditions:

$$q_t = 1 + \iota \left(\frac{K_t - K_{t-1}}{K_{t-1}} \right); \tag{A.10}$$

$$W_t = H_t^{\omega-1}. \tag{A.11}$$

Defining the borrowing cushion, B_t^*, as the difference between the amount of borrowing and the debt limit

$$B_t^* = \frac{1}{(1 + r_t)} B_t - \phi \left(1 + r_t\right) \left(W_t H_t + P_t V_t\right) + \kappa q_t K_t, \tag{A.12}$$

the regime-switching slackness condition is given by

$$\varphi\left(s_t\right) B_{ss}^* + \nu\left(s_t\right) \left(B_t^* - B_{ss}^*\right) = \left(1 - \varphi\left(s_t\right)\right) \lambda_{ss} + \left(1 - \nu\left(s_t\right)\right) \left(\lambda_t - \lambda_{ss}\right) \tag{A.13}$$

where $\varphi\left(s_t\right)$ and $\nu\left(s_t\right)$ are regime-switching parameters controlling the level and the dynamics of the economy, respectively, and B_{ss}^* and λ_{ss} are the regime-switching steady-state values of B_t^* and λ_t.

As we discussed in the text, the country interest rate and the exogenous processes are given by

$$r_t = r_t^* + \sigma_r \varepsilon_{r,t} + \psi_r \left(e^{\bar{B} - B_t} - 1\right) \tag{A.14}$$

where

$$r_t^* = \left(1 - \rho_{r^*}\right) \bar{r}^* + \rho_{r^*} r_{t-1}^* + \sigma_{r^*} \varepsilon_{r^*,t} \tag{A.15}$$

$$\log A_t = \rho_A \log A_{t-1} + \sigma_A \varepsilon_{A,t} \tag{A.16}$$

$$\log E_t = \left(1 - \rho_E\right) \log E^* + \rho_E \log E_{t-1} + \sigma_E \varepsilon_{E,t} \tag{A.17}$$

$$\log P_t = \left(1 - \rho_P\right) \log P^* + \rho_P \log P_{t-1} + \sigma_P \varepsilon_{P,t} \tag{A.18}$$

44

$$\log d_t = \rho_d \log d_{t-1} + \sigma_d \varepsilon_{d,t}, \tag{A.19}$$

where the errors terms $\varepsilon_{.,t}$ are i.i.d $N(0,1)$.

In the paper, we also use a number of auxiliary variables defined as as

$$\text{GDP: } Y_t = A_t K_{t-1}^{\eta} H_t^{\alpha} V_t^{1-\alpha-\eta} - P_t V_t \tag{A.20}$$

$$\text{Debt-to-GDP Ratio: } \Phi_t^b = \frac{B_t}{Y_t} \tag{A.21}$$

$$\text{Current Account-to-GDP Ratio: } \Phi_t^{ca} = \frac{B_t - B_{t-1}}{Y_t} \tag{A.22}$$

$$\text{Trade Balance-to-GDP Ratio: } \Phi_t^{tb} = \frac{Y_t - E_t - C_t - I_t}{Y_t} \tag{A.23}$$

$$\text{External Financing Premium on Debt: } EFPD_t = \frac{\lambda_t}{\beta \mathbb{E}_t \mu_{t+1}}. \tag{A.24}$$

A.2 Regime-Switching Equilibrium Definition

A competitive equilibrium of our economy is a sequence of quantities $\{K_t, B_t, C_t, H_t, V_t, I_t, A_t, E_t, B_t^*\}$ and prices $\{P_t, r_t^*, r_t, q_t, w_t, \mu_t, \lambda_t\}$ that, given the 5 exogenous processes (A.16)-(A.15), satisfy the first-order conditions for the representative household-firm (A.5)-(A.9), the market price equations (A.10)-(A.11), the market clearing conditions (A.2)-(A.3), the debt cushion definition (A.12), regime-switching slackness condition (A.13), and the equation for the interest rate (A.14).

Appendix B   Perturbation Solution Method

This Appendix provides details about two aspects of the solution method: (1) the definition of, and solution for, the steady state of the endogenous regime-switching economy; and (2) the perturbation method that generates second order Taylor expansions to the solution of the economy around the steady state.

45

B.1 Regime Switching Equilibrium

Write the 23 equilibrium conditions above as

$$\mathbb{E}_t f\left(\mathbf{y}_{t+1}, \mathbf{y}_t, \mathbf{x}_t, \mathbf{x}_{t-1}, \chi \varepsilon_{t+1}, \varepsilon_t, \theta_{t+1}, \theta_t\right) = 0. \tag{B.1}$$

Here $\mathbf{y}_t$ denotes the non-predetermined variables, $\mathbf{x}_t$ predetermined variables, ε_t the exogenous shocks, θ_t the regime-switching parameters, and χ the perturbation parameter. There are 7 predetermined variables

$$\mathbf{x}_{t-1} = \left[K_{t-1}, B_{t-1}, A_{t-1}, P_{t-1}, E_{t-1}, d_{t-1}, r^*_{t-1}\right] \tag{B.2}$$

and 16 non-predetermined variables

$$\mathbf{y}_t = \left[C_t, H_t, V_t, I_t, k_t, r_t, q_t, W_t, \mu_t, \lambda_t, B^*_t, Y_t, \Phi^b_t, \Phi^{ca}_t, \Phi^{tb}_t, EFPD_t\right], \tag{B.3}$$

with 6 exogenous shocks

$$\varepsilon_t = \left[\varepsilon_{A,t}, \varepsilon_{E,t}, \varepsilon_{P,t}, \varepsilon_{d,t}, \varepsilon_{r,t}, \varepsilon_{r^*,t}\right], \tag{B.4}$$

and 2 regime-switching parameters

$$\theta_t = \left[\varphi\left(s_t\right), \nu\left(s_t\right)\right]. \tag{B.5}$$

In general, the regime-switching parameters are partitioned into those that affect the steady state, $\theta_{1,t}$, and those that do not, $\theta_{2,t}$. In the case of our specific application, the partition is

$$\theta_{1,t} = \left[\varphi\left(s_t\right)\right] \qquad \theta_{2,t} = \left[\nu\left(s_t\right)\right]. \tag{B.6}$$

In order to solve the model, we assume the functional forms

$$\theta_{1,t+1} = \bar{\theta}_1 + \chi\hat{\theta}_1\left(s_{t+1}\right), \qquad \theta_{1,t} = \bar{\theta}_1 + \chi\hat{\theta}_1\left(s_t\right) \tag{B.7}$$

$$\theta_{2,t+1} = \theta_2\left(s_{t+1}\right), \qquad \theta_{2,t} = \theta_2\left(s_t\right) \tag{B.8}$$

$$\mathbf{x}_t = h_{s_t}\left(\mathbf{x}_{t-1}, \varepsilon_t, \chi\right) \tag{B.9}$$

46

$$\mathbf{y}_t = g_{s_t}\left(\mathbf{x}_{t-1}, \varepsilon_t, \chi\right), \qquad \mathbf{y}_{t+1} = g_{s_{t+1}}\left(\mathbf{x}_t, \chi\varepsilon_{t+1}, \chi\right) \tag{B.10}$$

and

$$\mathbb{P}_{s_t, s_{t+1}, t} = \pi_{s_t, s_{t+1}}\left(\mathbf{y}_t\right). \tag{B.11}$$

Now, substituting these functional forms in the 23 equilibrium conditions and being more explicit about the expectation operator, given $\left(\mathbf{x}_{t-1}, \varepsilon_t, \chi\right)$ and s_t, we have:

$$F_{s_t}\left(\mathbf{x}_{t-1}, \varepsilon_t, \chi\right) = \int \sum_{s'=0}^1 \pi_{s_t, s'}\left(g_{s_t}\left(\mathbf{x}_{t-1}, \varepsilon_t, \chi\right)\right) f \begin{pmatrix} g_{s_{t+1}}\left(h_{s_t}\left(\mathbf{x}_{t-1}, \varepsilon_t, \chi\right), \chi\varepsilon', \chi\right), \\ g_{s_t}\left(\mathbf{x}_{t-1}, \varepsilon_t, \chi\right), \\ h_{s_t}\left(\mathbf{x}_{t-1}, \varepsilon_t, \chi\right), \\ \mathbf{x}_{t-1}, \chi\varepsilon', \varepsilon_t, \\ \bar{\theta} + \chi\hat{\theta}\left(s'\right), \bar{\theta} + \chi\hat{\theta}\left(s_t\right) \end{pmatrix} d\mu\varepsilon'. \tag{B.12}$$

where $d\mu\varepsilon'$ denotes the joint pdf of the shocks.

Finally, stacking all conditions by regime yields:

$$\mathbb{F}\left(\mathbf{x}_{t-1}, \varepsilon_t, \chi\right) = \begin{bmatrix} F_{s_t=0}\left(\mathbf{x}_{t-1}, \varepsilon_t, \chi\right) \\ F_{s_t=1}\left(\mathbf{x}_{t-1}, \varepsilon_t, \chi\right) \end{bmatrix} = 0. \tag{B.13}$$

B.2 Steady State Definition and Solution

The model has two features that make defining a steady state challenging. First, as it is common in a regime-switching framework, some structural parameters may be switching. In the case of our application, there is only one switching parameter that affects the steady state, $\varphi\left(s_t\right)$. Nonetheless, in principle, one could allow for regime switching also in the parameters of the exogenous processes, $a^*\left(s_t\right)$ and $p^*\left(s_t\right)$, or the structural parameter $\kappa^*\left(s_t\right)$, which would affect the level of the economy and the steady state calculations.[27] Following Foerster et al. (2016), we define the steady state in terms of the ergodic means of these parameters across regimes. To define the steady state, we set $\varepsilon_t = 0$ and $\chi = 0$, which implies that the steady state is given by

$$f\left(\mathbf{y}_{ss}, \mathbf{y}_{ss}, \mathbf{x}_{ss}, \mathbf{x}_{ss}, 0, 0, \bar{\theta}_{\mathbf{1}}, \theta_2(s'), \bar{\theta}_1, \theta_2(s)\right) = 0 \tag{B.14}$$

---

[27] As it is well known, over finite periods of time, unit root processes and processes with structural break or regime changes are observationally equivalent from a statistical standpoint. Allowing for regime changes in the process for A_t, therefore, would be a way to accommodate permanent productivity shocks as in Aguiar and Gopinath (2007). Similarly, stochastic volatility could be allowed for by introducing regime switching in the some or all of the shock variances.

for all s', s.

In our case, the transition matrix evaluated at steady state $\mathbb{P}_{ss}$ is endogenous, since it depends on variables that in turn depend on the steady state value of the transition matrix. To find a solution for the steady state, we proceed in two steps. First, we assume the steady state transition matrix is known and solve for all the steady state prices and quantities. Second, we use the steady state values of the borrowing cushion B_{ss}^* and multiplier λ_{ss} from Step 1 to update the steady state transition matrix. We then iterate to convergence.

Step 1: Solve steady state using a given steady state transition matrix. First, assume that the steady state transition matrix at iteration i, $\mathbb{P}_{ss}^{(i)}$, is known. Next, let $\xi = [\xi_0, \xi_1]$ denote the ergodic vector of $\mathbb{P}_{ss}^{(i)}$. Then, as noted in the paper, define the ergodic means of the switching parameters as

$$\bar{\varphi} = \xi_0 \varphi(0) + \xi_1 \varphi(1).$$

The steady state of the regime-switching economy depends on these ergodic means, and we can now solve for the steady states of all variables. First, we can partially solve for some of the steady state directly

$$A_{ss} = 1, d_{ss} = 1, E_{ss} = E^*, P_{ss} = P^*, q_{ss} = 1, r_{ss}^* = \bar{r}^* \tag{B.15}$$

Suppose now that we knew r_{ss}. Then, we can obtain:

$$\Omega_v \equiv \frac{A_{ss} K_{ss}^\eta H_{ss}^\alpha V_{ss}^{1-\alpha-\eta}}{P_{ss} V_{ss}} = \frac{1 + \phi r_{ss} + \phi(1 + r_{ss})(1 - \beta(1 + r_{ss}))}{1 - \alpha - \eta} \tag{B.16}$$

$$\Omega_h \equiv \frac{A_{ss} K_{ss}^\eta H_{ss}^\alpha V_{ss}^{1-\alpha-\eta}}{W_{ss} H_{ss}} = \frac{1 + \phi(r_{ss} + (1 + r_{ss})(1 - \beta(1 + r_{ss})))}{\alpha} \tag{B.17}$$

$$\Omega_k \equiv \frac{A_{ss} K_{ss}^\eta H_{ss}^\alpha V_{ss}^{1-\alpha-\eta}}{K_{ss}} = \frac{1}{\eta}\left(\frac{1 - \kappa(1 - \beta(1 + r_{ss}))}{\beta} - 1 + \delta\right) \tag{B.18}$$

$$H_{ss} = \left(\frac{A_{ss}}{\Omega_k^\eta \Omega_h^\alpha (P_{ss}\Omega_v)^{1-\alpha-\eta}}\right)^{\frac{1}{\alpha(\omega-1)}} \tag{B.19}$$

$$V_{ss} \equiv \frac{\Omega_h}{P_{ss}\Omega_v} H_{ss}^\omega \tag{B.20}$$

$$K_{ss} = \frac{\Omega_h}{\Omega_k} H_{ss}^\omega \tag{B.21}$$

$$Y_{ss} = \Omega_h H_{ss}^{\omega} - P_{ss} V_{ss} \tag{B.22}$$

$$W_{ss} = H_{ss}^{\omega - 1} \tag{B.23}$$

$$I_{ss} = \delta K_{ss} \tag{B.24}$$

$$k_{ss} = K_{ss} \tag{B.25}$$

$$B_{ss} = \bar{B} - \log\left(1 + \frac{r_{ss} - r^*}{\psi_r}\right) \tag{B.26}$$

$$C_{ss} = Y_{ss} - \phi r_{ss} \left(W_{ss} H_{ss} + P_{ss} V_{ss}\right) - E_{ss} + B_{ss}\left(1 - \frac{1}{(1 + r_{ss})}\right) - I_{ss} \tag{B.27}$$

$$\mu_{ss} = \left(C_{ss} - \frac{H_{ss}^{\omega}}{\omega}\right)^{-\rho} \tag{B.28}$$

$$\lambda_{ss} = \left(1 - \beta\left(1 + r_{ss}\right)\right)\mu_{ss} \tag{B.29}$$

$$B_{ss}^* = \frac{1}{(1 + r_{ss})} B_{ss} - \phi\left(1 + r_{ss}\right)\left(W_{ss} H_{ss} + P_{ss} V_{ss}\right) + \kappa K_{ss} \tag{B.30}$$

$$\Phi_{ss}^b = \frac{B_{ss}}{Y_{ss}} \tag{B.31}$$

$$\Phi_{ss}^{ca} = 0 \tag{B.32}$$

$$\Phi_{ss}^{tb} = \frac{Y_{ss} - E_{ss} - C_{ss} - I_{ss}}{Y_{ss}} \tag{B.33}$$

$$EFPD_{ss} = \frac{\lambda_{ss}}{\beta \mu_{ss}}. \tag{B.34}$$

The variable r_{ss} can then be derived as the solution of

$$\bar{\varphi} B_{ss}^* = \left(1 - \bar{\varphi}\right) \lambda_{ss}. \tag{B.35}$$

Step 2: Updating the transition matrix. Step 1 yields the variables B_{ss}^* and λ_{ss}, and hence provides a new value of the transition matrix for iteration $i + 1$:

$$P_{ss}^{(i+1)} = \begin{bmatrix} p_{00,ss} & p_{01,ss} \\ p_{10,ss} & p_{11,ss} \end{bmatrix} = \begin{bmatrix} 1 - \frac{\exp(-\gamma_0 B_{ss}^*)}{1+\exp(-\gamma_0 B_{ss}^*)} & \frac{\exp(-\gamma_0 B_{ss}^*)}{1+\exp(-\gamma_0 B_{ss}^*)} \\ \frac{\exp(-\gamma_1 \lambda_{ss})}{1+\exp(-\gamma_1 \lambda_{ss})} & 1 - \frac{\exp(-\gamma_1 \lambda_{ss})}{1+\exp(-\gamma_1 \lambda_{ss})} \end{bmatrix}, \tag{B.36}$$

which can be checked against the guess in Step 1. We then iterate to convergence until

$$\left\| P_{ss}^{(i+1)} - P_{ss}^{(i)} \right\| < tolerance,$$

where in our application we use a tolerance of 10^{-10}.

B.3   Generating Approximations

To compute a second order approximation to the endogenous regime-switching model solution, we largely follow Foerster et al. (2016), adapting to the case with endogenous probabilities.

We take the stacked equilibrium conditions $\mathbb{F}(\mathbf{x}_{t-1}, \varepsilon_t, \chi)$, and differentiate with respect to $(\mathbf{x}_{t-1}, \varepsilon_t, \chi)$. The first-order derivative with respect to $\mathbf{x}_{t-1}$ produces a polynomial system denoted

$$\mathbb{F}_{\mathbf{x}}(\mathbf{x}_{ss}, \mathbf{0}, 0) = 0. \tag{B.37}$$

In Foerster et al. (2016), when the transition probabilities are exogenous and fixed, this system needs to be solved via Gröbner bases, which finds all possible solutions in order to check them for stability. The relevant stability concept is mean square stability (MSS), which requires the expectation of first and second moments to be finite (see Costa et al., 2005). In our case with endogenous probabilities, the check for MSS is not applicable, so we focus on finding a single solution and ignore the possibility of multiple solutions or indeterminacy, a common simplification in the regime-switching literature with and without endogenous switching (e.g. Farmer et al., 2011; Foerster, 2015; Maih, 2015; Lind, 2014). This simplification is also common to global solution methods of models with occasionally binding constraints, where numerical methods converge to a given solution but do not guarantee uniqueness of that solution. Instead, the focus typically is on checking robustness of the solution to initial conditions. While in some simpler models with collateral constraints it is possible to impose parametric restrictions that rule out multiple equilibria (Schmitt-Grohe and Uribe, 2020; Benigno et al., 2016), in the case of our model, as in Mendoza (2010) and Bianchi and Mendoza (2018), there are no such restrictions and uniqueness must be verified numerically.

To find a model solution, we guess a set of policy functions for regime $s_t = 1$, which reduces the equilibrium conditions $\mathbb{F}_{\mathbf{x}}(\mathbf{x}_{ss}, \mathbf{0}, 0; s_t = 0)$ to a fixed-regime eigenvalue problem, and solve for the policy functions for $s_t = 0$. Then, using this initial solution as a guess, we solve for regime $s_t = 0$ under the fixed-regime eigenvalue problem, and iterate to convergence. After solving the iterative eigenvalue problem, the remaining systems to solve are

$$\mathbb{F}_\varepsilon(\mathbf{x}_{ss}, \mathbf{0}, 0) = 0 \tag{B.38}$$

$$\mathbb{F}_\chi(\mathbf{x}_{ss}, \mathbf{0}, 0) = 0, \tag{B.39}$$

and the second order systems of the form

$$\mathbb{F}_{\mathbf{i},\mathbf{j}}(\mathbf{x}_{ss}, \mathbf{0}, 0) = 0, \ \mathbf{i}, \mathbf{j} \in \{\mathbf{x}, \varepsilon, \chi\}. \tag{B.40}$$

Recalling now that the decision rules have the form

$$\mathbf{x}_t = h_{s_t}(\mathbf{x}_{t-1}, \varepsilon_t, \chi) \tag{B.41}$$

$$\mathbf{y}_t = g_{s_t}(\mathbf{x}_{t-1}, \varepsilon_t, \chi), \tag{B.42}$$

the second-order approximation are

$$\mathbf{x}_t \approx \mathbf{x}_{ss} + H_{s_t}^{(1)} S_t + \frac{1}{2} H_{s_t}^{(2)}(S_t \otimes S_t) \tag{B.43}$$

$$\mathbf{y}_t \approx \mathbf{y}_{ss} + G_{s_t}^{(1)} S_t + \frac{1}{2} G_{s_t}^{(2)}(S_t \otimes S_t) \tag{B.44}$$

where $S_t = \left[(\mathbf{x}_{t-1} - \mathbf{x}_{ss})' \ \varepsilon_t' \ 1 \right]'$, with $\mathbf{x}_{ss}$ denoting the value of the steady-state variables.

B.4 Proposition 1: Irrelevance of Endogenous Switching in the First-Order Solution

To prove Proposition 1, take the first-order derivatives of (B.13) with respect to its arguments, evaluated at the steady state. This yields:

$$
\begin{aligned}
\mathbb{F}_{\mathbf{x},s_t}\left(\mathbf{x}_{ss},\mathbf{0},0\right) &= \sum_{s'} \pi_{s_t,s',y}\left(\mathbf{y}_{ss}\right) g_{\mathbf{x},s_t} f_{ss}\left(s',s_t\right) \\
&\quad + \sum_{s'} \pi_{s_t,s'}\left(\mathbf{y}_{ss}\right) \left[\begin{array}{c} f_{\mathbf{y}_{t+1}}\left(s',s_t\right) g_{\mathbf{x},s'} h_{\mathbf{x},s_t} + f_{\mathbf{y}_t}\left(s',s_t\right) g_{\mathbf{x},s_t} \\ + f_{\mathbf{x}_t}\left(s',s_t\right) h_{\mathbf{x},s_t} + f_{\mathbf{x}_{t-1}}\left(s',s_t\right) \end{array} \right]
\end{aligned}
\tag{B.45}
$$

$$
\begin{aligned}
\mathbb{F}_{\varepsilon,s_t}\left(\mathbf{x}_{ss},\mathbf{0},0\right) &= \sum_{s'} \pi_{s_t,s',y}\left(\mathbf{y}_{ss}\right) g_{\varepsilon,s_t} f_{ss}\left(s',s_t\right) \\
&\quad + \sum_{s'} \pi_{s_t,s'}\left(\mathbf{y}_{ss}\right) \left[\begin{array}{c} f_{\mathbf{y}_{t+1}}\left(s',s_t\right) g_{\mathbf{x},s'} h_{\varepsilon,s_t} + f_{\mathbf{y}_t}\left(s',s_t\right) g_{\varepsilon,s_t} \\ + f_{\mathbf{x}_t}\left(s',s_t\right) h_{\varepsilon,s_t} + f_{\varepsilon_t}\left(s',s_t\right) \end{array} \right]
\end{aligned}
\tag{B.46}
$$

and

$$
\begin{aligned}
\mathbb{F}_{\chi,s_t}\left(\mathbf{x}_{ss},\mathbf{0},0\right) &= \sum_{s'} \pi_{s_t,s',y}\left(\mathbf{y}_{ss}\right) g_{\chi,s_t} f_{ss}\left(s',s_t\right) \\
&\quad + \sum_{s'} \pi_{s_t,s'}\left(\mathbf{y}_{ss}\right) \left[\begin{array}{c} f_{\mathbf{y}_{t+1}}\left(s',s_t\right) g_{\mathbf{x},s'} h_{\chi,s_t} + f_{\mathbf{y}_t}\left(s',s_t\right) g_{\chi,s_t} \\ + f_{\mathbf{x}_t}\left(s',s_t\right) h_{\chi,s_t} \\ + f_{\theta_{t+1}}\left(s',s_t\right) \hat{\theta}\left(s_{t+1}\right) + f_{\theta_t}\left(s',s_t\right) \hat{\theta}\left(s_t\right) \end{array} \right]
\end{aligned}
\tag{B.47}
$$

Note now that, by definition of a steady state, $f_{ss}\left(s',s_t\right) = 0$, and so the first term of each of these expressions equals zero. Hence, we are left with the expressions for the exogenous transition probabilities as in Foerster et al. (2016), given by $\mathbb{P}_{ss} = \pi_{s_t,s'}\left(\mathbf{y}_{ss}\right)$. QED.

Appendix C Solution Accuracy and Comparison with Mendoza (2010)

In order to gauge the accuracy and speed of our solution method and evaluate the endogenous regime switching specification of the borrowing constraint relative to the traditional inequality one, we compare a suitably modified and calibrated version of our model to Mendoza (2010) solved with the FiPIt method of Mendoza and Villalvazo (2020).[28]

---

[28]See Binning and Maih (2017) for an analysis of the properties of our solution method applied to other structural models in which they found a high degree of accuracy.

Specifically, we compare our endogenous regime switching model solved with perturbation methods to the original Mendoza (2010) and a slightly different version solved with FiPIt by Mendoza and Villalvazo (2020). To do so, we calibrate the model at annual frequency, retaining only the three shocks in Mendoza (2010)—interest rate, productivity, and intermediate input price shocks—shutting down the expenditure and preference shocks and the temporary interest rate shock. We then compare simulated model moments, ergodic distributions of bond holding and capital, Euler equation errors, and solution speed.

We calibrate all common model parameters as in Mendoza and Villalvazo (2020). The parameters that are not common are the debt elasticity of the interest rate premium, which we set to 10^{-10}, and the logistic function parameters, which we set to $\gamma_0 = \gamma_1 = 1$. In principle, we could introduce a difference between the two logistic parameters, but for simplicity we focus on a symmetric calibration that roughly matches the probability of a positive multiplier on the total borrowing constraint. Both Mendoza (2010) and Mendoza and Villalvazo (2020) use finite state Markov processes, while we use discrete time autoregressive processes. We set our parameters so that the unconditional moments of the two set of processes coincide.

Table C.1 reports the results for all the moments across models. Comparing the first and second moments, we see that both the FiPIt solution method and our model solved with perturbation are very close to original Mendoza (2010), with the exception of the bond position to GDP. The ergodic mean of the bond position with FiPIt is much smaller than in Mendoza (2010), while it is slightly larger in our case. Similarly, the standard deviation is larger with FiPIt and smaller in our case.

As we can see from Figure C.1, our model's ergodic distribution is centered on a negative net foreign asset portion and more concentrated, while the FiPIt solution is centered on a net foreign asset position and more dispersed on the right side of the distribution tail. Although the shape of the bond distribution and the sudden stop statistics are very similar. We note here that Mexico's NFA position, from 1970 to 2015, averaged -37% of GDP and was never positive. Our model characterization of the data, therefore, is more accurate. Nonetheless, the volatility was 15%, and hence closer to the one obtained with FiPIt. As none of these three slightly different model specifications targeted these moments explicitly in the calibration, small differences are not surprising.

Figure C.2 also plots the decision rules of bonds and capital in the binding and the non-binding regimes of our model, evaluated at the steady state values of the technology, interest rate, and intermediate input price processes. The magnitude, dynamics, and frequency of financial crises depends critically on the behavior of these decision rules near and at the constraint. The decision rules show significant non-linearities along two dimension: the curvature in the non-binding regime and the difference in slope for the same value of the

state variable in the binding and non-binding regime. The curvature in the non-binding regime reflects how likely and how severely the credit constraint may be expected to bind at $t{+}1$ when it does not bind at time t. These policy functions clearly illustrate the ability of our model and its solution to capture the critical feature of the occasionally binding borrowing constraint.
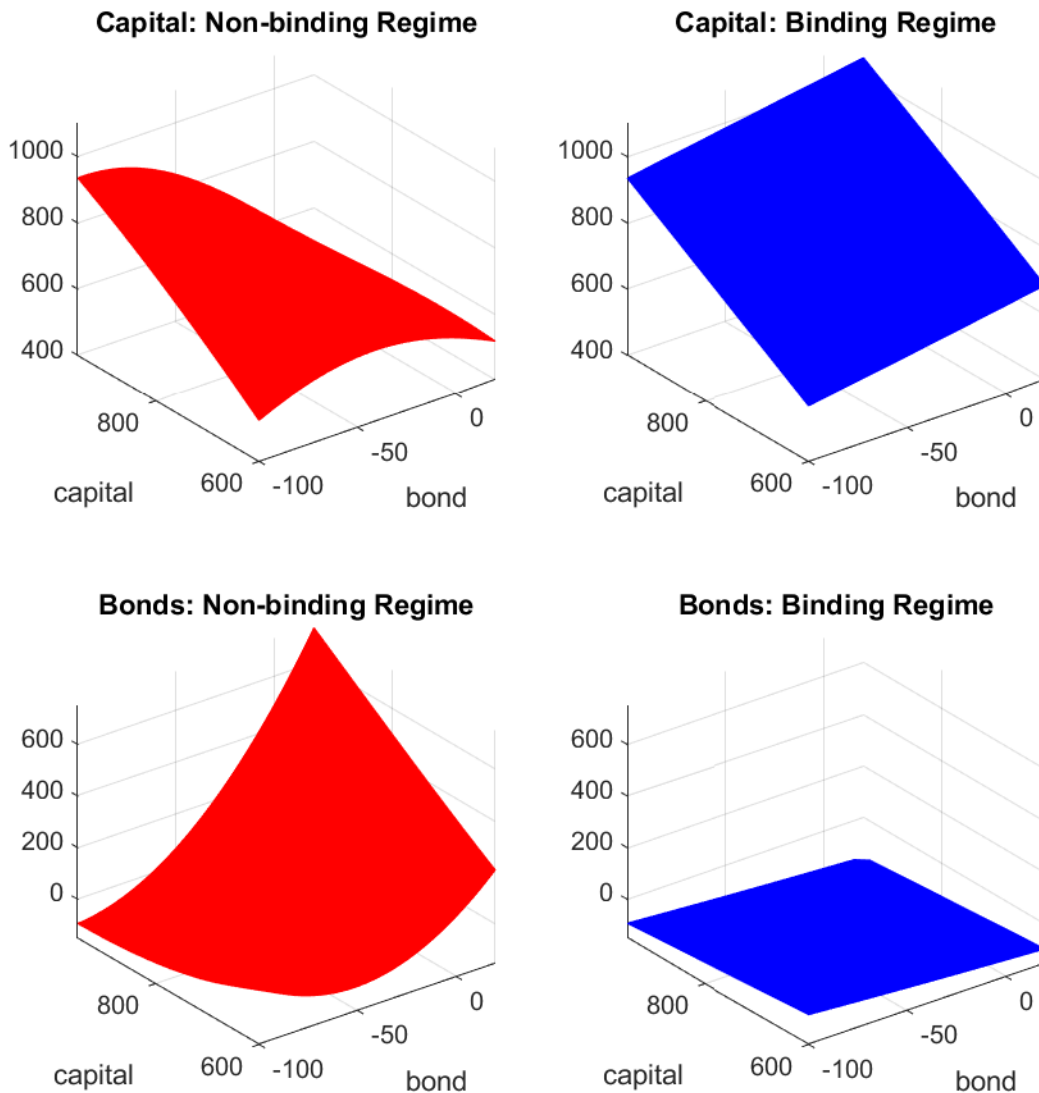

Figure C.1: Model Performance—Ergodic Distributions
Notes: Shows the simulated ergodic distribution of bonds and capital for the Mendoza and Villalvazo (2020) model using endogenous regime-switching.

Figure C.2: Model Performance—Decision Rules

Capital: Non-binding Regime

Capital: Binding Regime

Bonds: Non-binding Regime

Bonds: Binding Regime

Notes: Shows the decision rules for bonds and capital for the Mendoza and Villalvazo (2020) model using endogenous regime-switching.

Coming to compare performance metrics, it is evident from Table C.1 that there is a clear trade off between speed and accuracy. Our method is about 800 times faster than FiPIt, with log-10 absolute Euler equation errors that are only 2-3 times larger than FiPIt. The Euler equation errors for our method are in line with the values found solving exogenous regime switching models with perturbation methods (Foerster et al., 2016) and models without regime switching (Aruoba et al., 2006). To put these numbers in perspective, in

our estimation algorithm, the solution takes less than a second, and the filtering takes 9 seconds, meaning that each iteration takes 10 seconds. So, 500,000 MCMC iterations takes 5 million seconds, or about 58 days. With FiPIt, a solution time of 810 seconds would imply an iteration time of 819 seconds, and 500,000 MCMC iterations would take 409.5 million seconds, or about 4,740 days. On the other hand, the implied accuracy differences represent only around a dollar error per 1,000 dollars of consumption.

Appendix D   Bayesian Estimation Procedure

D.1   State Space

For likelihood estimation, the state space representation is

$$\mathcal{X}_t = \mathcal{H}_{s_t}\left(\mathcal{X}_{t-1}, \varepsilon_t\right) \tag{D.1}$$

$$\mathcal{Y}_t = \mathcal{G}_{s_t}\left(\mathcal{X}_t, \mathcal{U}_t\right) \tag{D.2}$$

where $\mathcal{X}_t$ denotes the state, $\mathcal{Y}_t$ denotes the observation, ε_t denotes the structural shocks, and $\mathcal{U}_t$ denotes the observation errors.

Recall the second-order approximation takes the form

$$\mathbf{x}_t \approx \mathbf{x}_{ss} + H^{(1)}_{s_t} S_t + \frac{1}{2} H^{(2)}_{s_t}\left(S_t \otimes S_t\right) \tag{D.3}$$

$$\mathbf{y}_t \approx \mathbf{y}_{ss} + G^{(1)}_{s_t} S_t + \frac{1}{2} G^{(2)}_{s_t}\left(S_t \otimes S_t\right) \tag{D.4}$$

where $S_t = \begin{bmatrix} (\mathbf{x}_{t-1} - \mathbf{x}_{ss})' & \varepsilon_t' & 1 \end{bmatrix}'$. Therefore, we can define the state variables as

$$\mathcal{X}_t = \begin{bmatrix} \mathbf{x}_t' & \mathbf{x}_{t-1}' & \mathbf{y}_t' & \mathbf{y}_{t-1}' & \epsilon_t \end{bmatrix}'. \tag{D.5}$$

The nonlinear transition equations,

$$\mathcal{X}_t = \mathcal{H}_{s_t}\left(\mathcal{X}_{t-1}, \varepsilon_t\right) \tag{D.6}$$

can be represented as

$$
\begin{bmatrix}
\mathbf{x}_t \\
\mathbf{x}_{t-1} \\
\mathbf{y}_t \\
\mathbf{y}_{t-1} \\
\varepsilon_t
\end{bmatrix}
=
\begin{bmatrix}
\mathbf{x}_{ss} + H_{s_t}^{(1)} S_t + \frac{1}{2} H_{s_t}^{(2)} \left(S_t \otimes S_t \right) \\
\mathbf{x}_{t-1} \\
\mathbf{y}_{ss} + G_{s_t}^{(1)} S_t + \frac{1}{2} G_{s_t}^{(2)} \left(S_t \otimes S_t \right) \\
\mathbf{y}_{t-1} \\
\varepsilon_t
\end{bmatrix}.
\tag{D.7}
$$

The observation equation

$$
\mathcal{Y}_t = \mathcal{G}_{s_t} \left(\mathcal{X}_t, \mathcal{U}_t \right)
\tag{D.8}
$$

is given by

$$
\begin{bmatrix}
\Delta y_t \\
\Delta c_t \\
\Delta i_t \\
r_t \\
\Delta B_t / Y_t \\
\Delta P_t
\end{bmatrix}
= D
\begin{bmatrix}
\mathbf{x}_t \\
\mathbf{x}_{t-1} \\
\mathbf{y}_t \\
\mathbf{y}_{t-1} \\
\varepsilon_t
\end{bmatrix}
+ \mathcal{U}_t
\tag{D.9}
$$

where D denotes a selection matrix of the form

$$
\begin{bmatrix}
\Delta y_t \\
\Delta c_t \\
\Delta i_t \\
r_t \\
\Delta B_t / Y_t \\
\Delta P_t
\end{bmatrix}
=
\begin{bmatrix}
0 & 0 & 1_{[y_t]} & -1_{[y_t]} & 0 \\
0 & 0 & 1_{[c_t]} & -1_{[c_t]} & 0 \\
0 & 0 & 1_{[i_t]} & -1_{[i_t]} & 0 \\
0 & 0 & 1_{[r_t]} & 0 & 0 \\
0 & 0 & 1_{[\Phi_t^{ca}]} & 0 & 0 \\
1_{[P_t]} & -1_{[P_t]} & 0 & 0 & 0
\end{bmatrix}
\begin{bmatrix}
\mathbf{x}_t \\
\mathbf{x}_{t-1} \\
\mathbf{y}_t \\
\mathbf{y}_{t-1} \\
\varepsilon_t
\end{bmatrix}
+ \mathcal{U}_t.
\tag{D.10}
$$

D.2   Filtering

To filter the likelihood, we use the Unscented Kalman Filter (UKF). The UKF calculates the state mean and covariance by propagating deterministically chosen sigma-points through the nonlinear functions. The transformed points are then used to calculate the mean and covariance matrix. As Julier and Uhlmann (1999) note, the critical assumption taken to apply the UKF is that the prediction density and the filtering density are both Gaussian.

The filtering and smoothing largely follow Binning and Maih (2015). The filter starts by combining the state vector and exogenous disturbances into a single vector, $\mathcal{X}_{t-1}^a = [\mathcal{X}_{t-1}, \epsilon_t]'$,

58

with the following mean and covariance matrix conditional on $Y_{1:t-1}$ and regime s_{t-1}:

$$\mathcal{X}_{t-1}^a(s_{t-1}) = \begin{bmatrix} \mathcal{X}_{t-1|t-1}(s_{t-1}) \\ 0_\epsilon \end{bmatrix} \tag{D.11}$$

$$P_{t-1}^a(s_{t-1}) = \begin{bmatrix} P_{t-1|t-1}^x(s_{t-1}) & 0 \\ 0 & I \end{bmatrix}. \tag{D.12}$$

The sigma-points $\mathcal{X}_{i,t-1}^a(s_{t-1})$ that consist of the sigma-points for state variables $\mathcal{X}_{i,t-1}^x(s_{t-1})$ and the sigma-points for exogenous shocks $\mathcal{X}_{i,t-1}^\varepsilon(s_{t-1})$ are chosen as follows:

$$
\begin{align}
\mathcal{X}_{0,t-1}^a(s_{t-1}) &= \mathcal{X}_{t-1}^a(s_{t-1}) \tag{D.13} \\
\mathcal{X}_{0,t-1}^a(s_{t-1}) &= \mathcal{X}_{t-1}^a(s_{t-1}) \tag{D.14} \\
\mathcal{X}_{i,t-1}^a(s_{t-1}) &= \mathcal{X}_{t-1}^a(s_{t-1}) + (h\sqrt{P_{t-1}^a(s_{t-1})})_i \text{ for } i = 1\ldots L \tag{D.15} \\
\mathcal{X}_{i,t-1}^a(s_{t-1}) &= \mathcal{X}_{t-1}^a(s_{t-1}) - (h\sqrt{P_{t-1}^a(s_{t-1})})_{i-L} \text{ for } i = L+1\ldots 2L, \tag{D.16}
\end{align}
$$

where $h = \sqrt{3}$ and L denotes the number of state variables and exogenous shocks. The weights for the sigma-points are given by:

$$
\begin{align}
w_0 &= \frac{h-L}{2h} \tag{D.17} \\
w_i &= \frac{1}{2h} \text{ for } i = 1\ldots 2L \tag{D.18}
\end{align}
$$

The sigma-points and the assigned weights are used to calculate the expected mean and covariance by propagating sigma-points through transition equations and taking weighted average:

$$\mathcal{X}_{i,t|t-1}(s_{t-1}, s_t) = H_{s_t}(\mathcal{X}_{i,t-1}^x(s_{t-1}), \mathcal{X}_{i,t-1}^\varepsilon(s_{t-1})) \tag{D.19}$$

$$\mathcal{X}_{t|t-1}(s_{t-1}, s_t) = \sum_{i=0}^{2L} w_i \mathcal{X}_{i,t|t-1}(s_{t-1}, s_t) \tag{D.20}$$

$$P_{t|t-1}^x(s_{t-1}, s_t) = \sum_{i=0}^{2L} w_i \tilde{\mathcal{X}}_i \tilde{\mathcal{X}}_i^T \tag{D.21}$$

$$\mathcal{Y}_{t|t-1}(s_{t-1}, s_t) = D\mathcal{X}_{t|t-1}(s_{t-1}, s_t) \tag{D.22}$$

where $\tilde{\mathcal{X}}_i = \mathcal{X}_{i,t|t-1}(s_{t-1}, s_t) - \mathcal{X}_{t|t-1}(s_{t-1}, s_t)$. From these conditions, we get the Gaussian approximation predictive density $p(\mathcal{X}_t|\mathcal{Y}_{1:t-1}, s_{t-1}, s_t) = N(\mathcal{X}_{t|t-1}(s_{t-1}, s_t), P_{t|t-1}^x(s_{t-1}, s_t))$.

The predictive density is then updated using the standard Kalman filter rule:

$$P^y_{t|t-1}(s_{t-1}, s_t) = DP^x_{t|t-1}(s_{t-1}, s_t)D^T + R \tag{D.23}$$

$$P^{xy}_{t|t-1}(s_{t-1}, s_t) = P^x_{t|t-1}(s_{t-1}, s_t)D^T \tag{D.24}$$

$$K_t(s_{t-1}, s_t) = P^{xy}_{t|t-1}(s_{t-1}, s_t)(P^y_{t|t-1}(s_{t-1}, s_t))^{-1} \tag{D.25}$$

$$\mathcal{X}_{t|t}(s_{t-1}, s_t) = \mathcal{X}_{t|t-1}(s_{t-1}, s_t) + K_t(s_{t-1}, s_t)(\mathcal{Y}_t - \mathcal{Y}_{t|t-1}(s_{t-1}, s_t)) \tag{D.26}$$

$$P^x_{t|t}(s_{t-1}, s_t) = P^x_{t|t-1}(s_{t-1}, s_t) - K_t(s_{t-1}, s_t)P^y_{t|t-1}(s_{t-1}, s_t)K^T_t(s_{t-1}, s_t) \tag{D.27}$$

This updating step gives $p(\mathcal{X}_t|\mathcal{Y}_{1:t}, s_{t-1}, s_t) = N(\mathcal{X}_{t|t}(s_{t-1}, s_t), P^x_{t|t}(s_{t-1}, s_t))$. As a by-product of the filter, we can get the density of $\mathcal{Y}_t$ conditional on $\mathcal{Y}_{1:t-1}$, s_t, and s_{t-1}

$$p(\mathcal{Y}_t|\mathcal{Y}_{1:t-1}, s_{t-1}, s_t; \theta) = N(\mathcal{Y}_{t|t-1}(s_{t-1}, s_t), P^y_{t|t-1}(s_{t-1}, s_t)) \tag{D.28}$$

Since the Unscented Kalman filter with regime switches creates a large number of nodes at each iteration where the filtered mean and covariance matrix need to be evaluated, we implement the following collapsing procedure suggested by Kim and Nelson (1999)

$$\mathcal{X}_{t|t}(s_t = j) = \frac{1}{\Pr(s_t = j|\mathcal{Y}_{1:t})}\left\{\sum_{i=1}^M \Pr(s_{t-1} = i, s_t = j|\mathcal{Y}_{1:t})\mathcal{X}_{t|t}(s_{t-1} = i, s_t = j)\right\} \tag{D.29}$$

$$P^x_{t|t}(s_t = j) = \frac{1}{\Pr(s_t = j|\mathcal{Y}_{1:t})}\left\{\sum_{i=1}^M \Pr(s_{t-1} = i, s_t = j|\mathcal{Y}_{1:t})[P^x_{t|t}(s_{t-1} = i, s_t = j)\right. \tag{D.30}$$
$$\left. + (\mathcal{X}_{t|t}(s_t = j) - \mathcal{X}_{t|t}(s_{t-1} = i, s_t = j))(\mathcal{X}_{t|t}(s_t = j) - \mathcal{X}_{t|t}(s_{t-1} = i, s_t = j))^T]\right\}$$

where $\Pr(s_t, s_{t-1}|\mathcal{Y}_{1:t})$ and $\Pr(s_t|\mathcal{Y}_{1:t})$ are obtained from the following Hamilton filter

$$\Pr(s_t, s_{t-1}|\mathcal{Y}_{1:t-1}) = \Pr(s_t|s_{t-1})\Pr(s_{t-1}|\mathcal{Y}_{1:t-1}) \tag{D.31}$$

$$\Pr(s_t, s_{t-1}|\mathcal{Y}_{1:t}) = \frac{p(\mathcal{Y}_t|s_t, s_{t-1}, \mathcal{Y}_{1:t-1})\Pr(s_t, s_{t-1}|\mathcal{Y}_{1:t-1})}{\sum_{s_t}\sum_{s_{t-1}} p(\mathcal{Y}_t|s_t, s_{t-1}, \mathcal{Y}_{1:t-1})\Pr(s_t, s_{t-1}|\mathcal{Y}_{1:t-1})} \tag{D.32}$$

$$\Pr(s_t|\mathcal{Y}_{1:t}) = \sum_{s_{t-1}} \Pr(s_t, s_{t-1}|\mathcal{Y}_{1:t}). \tag{D.33}$$

The resulting conditional marginal likelihood is

$$p(\mathcal{Y}_t|\mathcal{Y}_{1:t-1}; \theta) = \sum_{s_t} \sum_{s_{t-1}} p(\mathcal{Y}_t|s_t, s_{t-1}, \mathcal{Y}_{1:t-1}) \Pr(s_t, s_{t-1}|\mathcal{Y}_{1:t-1}). \tag{D.34}$$

D.3 Smoothing

Once we perform the filtering using the UKF for $t = 1, \ldots, T$, we can also obtain $\Pr(s_t, s_{t+1}|\mathcal{Y}_{1:T})$, $\Pr(s_t|\mathcal{Y}_{1:T})$, $x_{t|T}(s_t, s_T)$, and $P_{t|T}^x(s_t, s_T)$:

$$\Pr(s_t, s_{t+1}|\mathcal{Y}_{1:T}) = \frac{\Pr(s_{t+1}|\mathcal{Y}_{1:T}) \Pr(s_t|\mathcal{Y}_{1:t}) \Pr(s_{t+1}|s_t)}{\Pr(s_{t+1}|\mathcal{Y}_{1:t})} \tag{D.35}$$

$$\Pr(s_t|\mathcal{Y}_{1:T}) = \sum_{s_{t+1}} \Pr(s_t, s_{t+1}|\mathcal{Y}_{1:T}) \tag{D.36}$$

$$\mathcal{X}_{t|T}(s_t, s_{t+1}) = \mathcal{X}_{t|t}(s_t) + \tilde{K}_t(s_t, s_{t+1})(\mathcal{X}_{t+1|T}(s_{t+1}) - \mathcal{X}_{t+1|t}(s_t, s_{t+1})) \tag{D.37}$$

$$P_{t|T}^x(s_t, s_{t+1}) = P_{t|t}^x(s_t) - \tilde{K}_t(s_t, s_{t+1})(P_{t+1|T}^x(s_{t+1}) - P_{t+1|T}^x(s_t, s_{t+1}))\tilde{K}_t(s_t, s_{t+1})^T$$

Given the above smoothing algorithm, we implement a collapsing procedure similar to those in the filtering step:

$$\mathcal{X}_{t|T}(s_t = j) = \frac{1}{\Pr(s_t = j|\mathcal{Y}_{1:T})} \left\{ \sum_{j=1}^{M} \Pr(s_t = i, s_{t+1} = j|\mathcal{Y}_{1:T}) \mathcal{X}_{t|T}(s_t = i, s_{t+1} = j) \right\}, \tag{D.38}$$

$$P_{t|T}^x(s_t = j) = \frac{1}{\Pr(s_t = j|\mathcal{Y}_{1:T})} \left\{ \sum_{j=1}^{M} \Pr(s_t = i, s_{t+1} = j|\mathcal{Y}_{1:T})[P_{t|T}^x(s_t = i, s_{t+1} = j) \right.$$

$$\left. + (\mathcal{X}_{t|T}(s_t = j) - \mathcal{X}_{t|T}(s_t = i, s_{t+1} = j))(\mathcal{X}_{t|T}(s_t = j) - \mathcal{X}_{t|T}(s_t = i, s_{t+1} = j))^T] \right\}. \tag{D.39}$$

Appendix E   Calibrated Parameters

To calibrate the parameters that we do not estimate, we largely follow Mendoza (2010), targeting the same moments, but adapting the computations to our model specification. We start by calibrating certain parameters based on the steady state of the model without working capital and the borrowing constraint—i.e., with $\phi = 0$ and $\bar{\varphi} = 0$, which implies

$\lambda_{ss} = 0$. In addition, we set

$$\beta \left(1 + r_{ss}\right) = 1, \tag{E.1}$$

and

$$\Omega_v = \frac{1}{1 - \alpha - \eta}, \; \Omega_h = \frac{1}{\alpha}, \; \Omega_k = \frac{1}{\eta}\left(\frac{1}{\beta} - 1 + \delta\right). \tag{E.2}$$

The implied factor payment ratios are

$$\frac{P_{ss}V_{ss}}{Y_{ss} + P_{ss}V_{ss}} = \frac{1}{\Omega_v} = 1 - \alpha - \eta \tag{E.3}$$

$$\frac{W_{ss}H_{ss}}{Y_{ss}} = \frac{1}{\Omega_h\left(1 - \frac{1}{\Omega_v}\right)} = \frac{\alpha}{\alpha + \eta} \tag{E.4}$$

$$\frac{\left(\frac{1}{\beta} - 1 + \delta\right)K_{ss}}{Y_{ss}} = \frac{\frac{1}{\beta} - 1 + \delta}{\Omega_k\left(1 - \frac{1}{\Omega_v}\right)} = \frac{\eta}{\alpha + \eta}. \tag{E.5}$$

Using the National Accounts, we obtain

$$\begin{bmatrix} 1 - \alpha - \eta = 0.102 \\ \frac{\alpha}{\alpha+\eta} = 0.66 \end{bmatrix} \Longrightarrow \begin{bmatrix} \alpha = 0.59268 \\ \eta = 0.30532 \end{bmatrix}. \tag{E.6}$$

We then set the depreciation rate to an annual value of 8.8 percent, so that

$$(1 - \delta)^4 = 1 - 0.088 \Longrightarrow \delta = 0.022766. \tag{E.7}$$

The capital-to-(gross annual) output ratio is 1.758, so the capital-to-(gross quarterly) output ratio, Ω_k^{-1}, implies

$$\Omega_k^{-1} = \left(\frac{1}{\eta}\left(\frac{1}{\beta} - 1 + \delta\right)\right)^{-1} = 4 * 1.758 \Longrightarrow \beta = 0.97977. \tag{E.8}$$

In turn, this yields an annualized real interest rate of

$$(1 + r_{ss})^4 = \left(\frac{1}{\beta}\right)^4 = 1.0852, \tag{E.9}$$

which is very close to the value used in Mendoza (2010), but it is obtained under different discounting assumptions. From the resource constraint,

$$\frac{C_{ss}}{Y_{ss}} + \frac{I_{ss}}{Y_{ss}} + \frac{E_{ss}}{Y_{ss}} = 1 + \left(1 - \frac{1}{1 + r_{ss}}\right)\frac{B_{ss}}{Y_{ss}}, \tag{E.10}$$

we obtain

$$0.65 + 0.172 + 0.11 = 1 + (1 - \beta)\frac{B_{ss}}{Y_{ss}} \implies \frac{B_{ss}}{Y_{ss}} = -3.3605. \tag{E.11}$$

This implies

$$\frac{B_{ss}}{4Y_{ss}} = -0.840127, \tag{E.12}$$

from which we have

$$Y_{ss} = \frac{\alpha + \eta}{\alpha}\left(\frac{1}{P_{ss}^{1-\alpha-\eta}\left(\frac{1}{\eta}\left(\frac{1}{\beta} - 1 + \delta\right)\right)^{\eta}\left(\frac{1}{\alpha}\right)^{\alpha}\left(\frac{1}{1-\alpha-\eta}\right)^{1-\alpha-\eta}}\right)^{\frac{\omega}{\alpha(\omega-1)}} = 1.8202, \tag{E.13}$$

and

$$E^* = \frac{E_{ss}}{Y_{ss}}Y_{ss} = 0.11 * 1.8202 = 0.20022, \tag{E.14}$$

as well as

$$B_{ss} = -0.840127 * 4 * 1.8202 = -6.11685. \tag{E.15}$$

Finally, conditional on r^* and ψ_r, $\bar{B}$ is pinned down via

$$\bar{B} = \log\left(1 + \frac{r_{ss} - r^*}{\psi_r}\right) + B_{ss}. \tag{E.16}$$

Appendix F   Data Appendix

National accounts are from the National Statistic Office. The data series used in the analysis merge two sets of official statistics by updating the level of the accounts based on 1993 constant prices with the quarterly rate of growth of the accounts based on 2008 constant prices. The merging is necessary as the deflators to splice the accounts in levels were not available at the time of last download of the data (May 2017). The two sets of national accounts overlap from 1993:Q1 to 2006:Q4. Over this period, the difference in annual rate of growth is less than 0.01 percent in absolute value for GDP, less than 0.05 percent for consumption, less than 2 percent for investment, and less than 1 and 3 percent for imports and exports, respectively. The correlations between the series are more than 0.9 for all series except investment that is 0.84, pointing to possibly larger measurement errors in this

variable. The differences are smaller the closer to the end of the sample. For this reason, we choose to update the 1993 accounts rather than backdate the 2008 ones.

The specific sources of the data are as follows:

- 1980:Q1-2006:Q4 (Labeled 1993 accounts)—Supply and demand of goods and services. Original Series (not seasonally adjusted). Constant prices, annual 1993 = 100. We obtained these from the Central Bank of Mexico (Gabriel, 2008).

- 2006:Q1-2016:Q4 (Labeled 2008 accounts)—Supply and demand of goods and services. Original series (not seasonally adjusted). Constant prices, annual 2008 = 100 (Oferta y demanda de bienes y servicios. Series originales. A precios constantes 2008). Available from http://www3.inegi.org.mx/sistemas/tabuladosbasicos/tabdirecto.aspx.

The data are not seasonally adjusted and show a strong seasonal pattern. To seasonally adjust all series (assumed to be I(1) processes), we adjust the log-difference using the X-12 procedure with the additive option in Eviews. We then use the log of the first observation of the raw series (not seasonally adjusted) and cumulate the seasonally adjusted log-difference. The net exports to GDP series, used to validate the model externally but not as an observable variable in estimation, is calculated as real exports minus real imports divided by real GDP.

The current account as a percentage of GDP is from the balance of payment statistics, obtained from the OECD Economic Outlook Database (Series MEX.CBGDPR.Q, OECD-EO-MEX-CBGDPR-Q).

As a proxy for the relative price of intermediate goods, entered as observable in estimation, we use a measure of Mexico's terms of trade obtained from Banco de Mxico (PPI Producer and International Trade Price Indexes, series SP12753).

Mexico's country interest rate is calculated following Uribe and Yue (2006) as

$$r_t = r_t^* + spread_t \tag{F.1}$$

where r^* is the US real interest rate, and *spread* is a proxy for Mexico's country risk or sovereign spread. We compute r^* as 3-month Treasury Constant Maturity Rate adjusted for ex post CPI (annualized) quarterly inflation, using period average data. The source of these data is FRED. For the country spread, as customary, we use the Mexico's component of the JP Morgan EMBI.

Unfortunately, the EMBI spread is available only starting from 1993. In order to estimate the country spread before 1993, we rely on empirical modeling of the relation between *domestic* real interest rates and country risk at the Banco de Mexico (Aportela Rodriguez et al., 2001) that estimates a close and stable relation between a measure of the domestic

64

real interest rate and the EMBI spread over the period over which both these variables are available. The only quarterly interest series available we are aware off going back to 1980 is a three-month nominal short-term rate obtained from Banco de Mexico (Average monthly yield on 90-days Cetes, series SF3338).[29] So we estimate a relationship between this nominal interest rate, i_t, and the EMBI during the period over which the EMBI is observable, adjusting for inflation, π_t, which was an important source of nominal interest rate variation in the 1980s, and then invert it. Specifically, we posit the following simplified version of the model that (Aportela Rodriguez et al., 2001) estimate:

$$i_t = \alpha_0 + \alpha_1 \pi_t + \alpha_2 EMBI_t. \tag{F.2}$$

We then solve the fitted equation for the country risk component of the domestic real interest rate, which we denote as $E\hat{M}BI_t$. The estimated regression is (t-statistics in parentheses and $R^2 = 0.883$):

$$\hat{i}_t = \underset{(-0.42)}{-0.00346} + \underset{(4.46)}{0.397}\pi_t + \underset{(7.37)}{2.770}E\hat{M}BI_t. \tag{F.3}$$

Appendix G   Additional Estimation Results

In this appendix we report additional empirical results.

G.1   Estimated Shocks and Transition Probabilities

Figure G.1 plots the pseudo-real-time (i.e. filtered) estimated transition probabilities. Panel (a) plots the probability of switching from the non-binding to the binding regime, while Panel (b) plots the probability of switching from the binding to the non-binding regime. In other words, they plot the estimated counterpart of the transition probabilities together with the model identified crisis peaks. These probabilities provide the odds of switching from one regime to the other as the model travels through the sample. Their behavior is driven by the estimated parameters γ_0 and γ_1 and the estimated values of B^* and λ. Both probabilities are time-varying and hence suggest that a model with exogenous and constant switching probabilities would be misspecified.

---

[29]There are three missing monthly observations in this series: August and September 1986 and November 1988. We fill these gaps using July 1986 for 1986Q3 and the average of October and December 1988 for 1988:Q4.

Figure G.1: Transition Probabilities

(a) Transition Probability of Binding Given Non-Binding

(b) Transition Probability of Non-Binding Given Binding
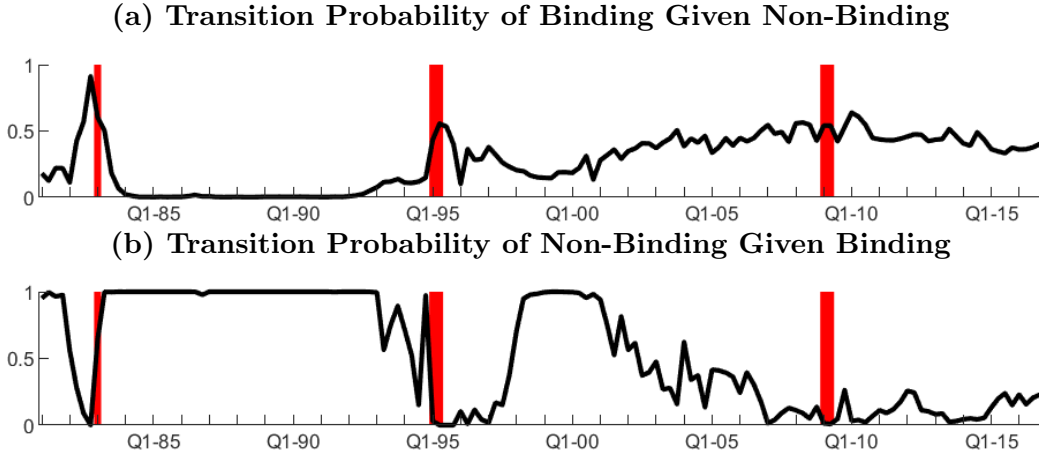

Notes: The top panel shows the model-implied filtered probability of transitioning into the binding regime in the subsequent period, conditional on being in the non-binding regime in the current period. The bottom panel shows the filtered probability of transitioning to the non-binding regime, conditional on being in the binding regime. Red bars indicate model-identified crisis peaks defined in the paper.

G.2 Assessing the Relative Importance of Shocks: A Likelihood-based Indicator

To study the importance of shocks before, after, and during financial crises episodes we construct an indicator of relative importance of each shock. Let LL denote the maximized log-likelihood over the full sample, and let $CLL_{i,t}$ denote the counterfactual full-sample log likelihood when shock i is set to zero in quarter t (i.e. $\varepsilon_{i,t} = 0$). The loss of fit in terms of likelihood points,

$$\Delta_{i,t} = LL - CLL_{i,t}, \tag{G.1}$$

can be interpreted as an measure of importance of $\varepsilon_{i,t}$.

Figure G.2 shows how this measure evolves. There is an obvious shortcoming to this measure: since we are computing the difference in the likelihood over the full sample, earlier observations tend to have larger values of $\Delta_{i,t}$ due to the fact that they impact all subsequent quarters. Hence, we compute a measure of relative importance. The importance of $\varepsilon_{i,t}$ relative to other shocks at time t can be assessed as

$$\Lambda_{i,t} = \frac{\Delta_{i,t}}{\sum_j \Delta_{j,t}}, \tag{G.2}$$

where the denominator of this expression cumulates the losses across all shocks. In the paper, we report this measure of average relative importance in a given subsample period of

66

Figure G.2: Historical Importance of Shocks, Log Points
Notes: For each quarter, shows the likelihood contribution (in log points) for each shock, computed by setting the given shock to zero in the given quarter.

T quarters, $(t + T) - (t)$, compared to the full sample averages, $\bar{\Lambda}_i$. Thus, the subsample measure reported in the main text can be computed by $\sum_{t=t_0}^{t_1} \Lambda_{i,t} - \bar{\Lambda}_i$. Note here that, similar to our variance decomposition results, this calculation ignores the non-linearities captured by the second-order solution.
